The properties of the smaller arteries are so very different from those of the vessels we have just been considering, that it is impossible to arrive at any satisfactory conclusion as to the effects induced in the former by the lateral pressure of the arterial blood, without determining and bearing in mind their distinctive peculiarities. They form a series of minute porous tubes, the coats of which, being highly contractile, are, in their healthy state, continually resisting the dilating pressure of the contained blood. In their relation, therefore, to that contained fluid, they represent so many rigid tubes. In them there is consequently no considerable accumulation of blood, nor do we find any functions performed by the elas-

* An experiment with the hemodynamometer, on the renal artery, which arises from the aorta at a right angle, would remove all doubt on this point.

ticity of their investing tissues. But other and still more important effects are here induced by the lateral pressure of the arterial blood, for by the operation of this force there is a constant exudation of certain portions of the blood through the thin and porous coats of these minute vessels. For proofs, that compression of the blood in its smaller vessels will cause its effusion through the coats of the latter, and that the nature of this effusion is mainly regulated by the degree of that compression, I beg to refer to a paper contained in the last volume of the *Medico-Chirurgical Transactions*: in it will be found an account of some experiments in which, on directing an increased flow of blood through one renal artery (by obstructing the abdominal aorta and the blood-vessels of the other kidney), various component parts of the blood, viz., liquid albumen, fibrinous and coloured coagula, were found in the secretion of the organ thus inordinately supplied.

But the observation which bears most directly on the present point is this—that on examining these hypertrophied kidneys at the end of a few hours, I generally found the primary divisions of the renal artery imbedded in a quantity of liquor sanguinis, which the unnatural compression of the contained blood had expelled through their porous coats. Since, therefore, an additional degree of compression of the blood is capable of forcing its most viscid parts through the coats of vessels which, from their thickness, must oppose a very great resistance to the passage of fluid through their pores, we cannot, I think, avoid the conclusion, that a constant, though slow, and, to the naked eye, imperceptible, process of albuminous effusion through the thin porous coats of the minute arteries, is a necessary consequence of the existence in each of them of a distending column of blood. This process of effusion must necessarily take place whenever the pressure acting on the internal surface of the membranous tube is greater than that of the medium in which the tube or vessel is placed. And if, at any one point, the resistance of the medium be less than the outward or lateral pressure of the contained fluid, then effusion will occur at that point only. For so long as an amount of pressure greater than the dilating or

lateral force of the contained fluid is applied on the external surface of a porous tube, the escape of that fluid through these minute lateral openings is evidently rendered as impossible as though the latter did not exist at all. In the living body the different tissues situated between the smaller blood-vessels will represent the medium in which the latter are placed; and its resistance is evidently insufficient wholly to repress, though it probably limits within certain bounds, the tendency to effusion resulting from the compression of the blood in the smaller arteries. There is, therefore, from this source, a constant effusion of albuminous fluid into the intervascular spaces, and a supply of their proper nutriment is thus brought in immediate contact with the tissues of the body.

The absolute force of the lateral pressure of the blood contained in the smaller arteries of a particular part, will, equally with that of its onward pressure, be affected by any change in the area of the main arterial branch supplying them. Whatever, then, increases the supply of blood to a part, will, at the same time, increase the amount of lateral pressure acting on the inner surface of the coats of the small arteries of that part. The functions to which that lateral pressure is there subservient must consequently, at this time also, be performed with unusual activity. And this reasoning is fully corroborated by the connection invariably observed in health and in disease between the activity of the nutritive process and the rate of supply of blood to a part, as estimated by the number and calibre of the arterial trunks connected with it.

A similar preponderance of the pressure acting on the internal surface of the coats of the smaller arteries will undoubtedly assist in causing that separation or exudation of certain portions of the blood which constitutes the first stage in the processes of secretion and excretion. But as the capillaries, or intermediate vessels, are generally considered to exercise a still more important influence in the performance of these functions, it becomes necessary to consider how far the preceding views are applicable to this part of the circulating system. And on considering the endless varieties that are observed to prevail in different organs of the body,

in respect to the relative length, number, arrangement, and connection of these vessels with the adjacent arteries and veins, the following are those conclusions which appear to derive the greatest amount of support from the knowledge already possessed on the subject. Wherever, in an arborescent arrangement of vessels, the blood flows from a main branch into numerous collateral twigs, it must encounter more or less obstruction during its passage through the latter, and will consequently continue to exert a certain amount of lateral pressure until it has traversed the most contracted portion of the tubes. In those organs where a peculiar disposition of the vessels impedes the flow of blood from the capillaries into the veins, the same effect, viz., an increase in the lateral pressure of the capillary streams, must follow the diminished rate of discharge from the capillaries thus induced. The causes of this partial obstruction may be seated either in the capillaries themselves, or in the adjacent veins. In some organs, as in the Malpighian tufts of the kidney, their own arrangement is a considerable source of obstruction to the blood traversing the former vessels. And in other parts, a tortuous course of the neighbouring veins, gravity, or any other cause which impedes the return of venous blood, must, at the same time, induce a corresponding increase in the amount of lateral pressure of the blood contained in the capillaries supplying those veins. But it is chiefly in secreting structures that a disposition of parts so unfavourable to the free circulation of the blood through the capillaries is observed to occur. And on applying to these cases the law frequently referred to, viz., that any impediment to the passage of a fluid increases the amount of its lateral pressure, how are we to avoid the conclusion that this peculiar physical condition of the blood contained in the capillaries of secreting organs is a provision of nature for the accomplishment of the necessary exudation of certain portions of that compressed fluid? The blood contained in the capillaries of different parts of the body must therefore exert different degrees of lateral pressure according as the impediments to its passage into the veins are more or less considerable. An opinion formerly prevailed, sup-

ported by Keil, Hales, and other physiologists, that the extraordinary impediments to the free return of the venous blood, which are almost invariably observed in organs whose natural secretion is highly albuminous, are, in some way or other, connected with that peculiarity in the secreted fluid. Our knowledge of the minute anatomy of some of these organs is perhaps too imperfect to justify a positive conclusion on the subject. But the relative viscosity of an effused fluid being, by the facts before referred to, shown to depend upon the degree of compression endured by the blood contained in the small vessels; and the anatomical arrangement of the blood-vessels of these glands furnishing the impediment necessary for the compression of the blood circulating through them; these two considerations do appear to me sufficient to invest the old doctrine with a certain degree of probability. Physiologists are too unsettled in their views of the process of secretion to render necessary many additional remarks in applying the general law of effusion to this particular function. For whether the secreted matters be derived directly from the blood by a process of filtration, or are the results of various chemical changes effected in that effused fluid by the peculiar physical conditions to which it is subjected previous to its final discharge, or are generated according to vital laws in cells developed by vital powers similar to those concerned in the process of growth, or, as is perhaps most probable, by the conjoint operation of all these agencies, it is in each case equally evident that a constant supply of material will be required; and this supply can only be obtained from the blood-vessels of the secreting structure. It is unnecessary to recapitulate any of the former arguments for the purpose of proving that this effusion is due to the expelling force constituted by the lateral pressure of the blood contained in these vessels. But in closing this part of my subject, I may remark—1st, That the free surface on which secretion invariably occurs is another provision for facilitating the process of effusion, by substituting a less resisting for a denser medium: so that the vessels are less firmly supported on that side than on the rest of their circumference. The influence of a

free surface, or of a loose structure, in facilitating effusion, is also strikingly exemplified in many of the phenomena of disease, and is clearly referrible to the diminished pressure then acting on the exterior of the minute blood-vessels: and, 2dly, that the different degrees of compression which the blood endures in the capillaries of different glands will probably exercise considerable influence in modifying the nature of their secretion.

The capillaries distributed throughout the rest of the body will, at their junctions with the minute arteries, assist the latter in the performance of the function of nutrition. The extent to which their share is limited, must, in each organ or structure, be mainly regulated by the relative facilities afforded to the passage of the blood into and from them. But in the following division of this memoir I shall mention some reasons in support of the opinion, that these vessels, more especially their terminating portions, are intimately connected with the adjacent venous radicles in the performance of the opposite function of absorption.

It may by some be considered that the foregoing views have too great a tendency to withdraw the functions of secretion and nutrition from the sphere of influence of the nervous system. But as it is generally acknowledged that the nerves possess the power of affecting the contractility of the blood-vessels so as to increase or diminish their calibre, and also that of the pores existing in their walls; and as that increase or diminution in the relative size of different portions of the blood-vessels of an organ must necessarily be followed by corresponding changes in the amount of lateral pressure acting on the internal surface of those vessels: this doctrine is in reality calculated to establish a still more intimate connection between the nervous system and these functions, by showing how the former is enabled to control the activity, and, at the same time, to modify to a certain extent the character, of the latter. I have now successively endeavoured to prove—

1. That the obstacles to the free passage of the arterial blood prevent the small arteries from discharging into the veins more than a limited quantity of blood in a given time.

2. That as the blood encounters fewer impediments in flowing into, than in escaping from, the arterial system, its rate of influx has a constant tendency to preponderate over its rate of efflux into the veins.

3. That the amount of this disproportion is ever varying; and that the evils which a great excess would occasion are probably in some measure obviated by the circumstance of the opposition to the influx of blood into the arterial system increasing in a direct ratio to the amount of disproportion between it and the rate of the efflux of blood into the veins.

4. That the whole mass of blood contained in the arterial system, from the heart to the most contracted portion of the capillaries, exerts a lateral pressure, the degree of which is altogether dependent upon the relative facilities afforded to the entrance of blood into, and its discharge from, that system of vessels.

5. That the lateral pressure of the blood contained within the arteries is probably equal to its onward pressure, so that the arterial blood will press equally in all directions.

6. That this lateral pressure of the arterial blood is the force which maintains the large arteries in a state of distension, and thus enables their elastic walls so to re-act upon their contents as to be the means of accomplishing various useful purposes in the animal economy.

7. That the same force acting on the interior of the minute porous arteries causes that slight but constant exudation of certain portions of the blood which is indispensable to the performance of the important functions of secretion and nutrition.

8. That the blood contained in the commencement of the capillaries being subservient to the same uses, is also made to exercise some lateral pressure, the degree of which varies in different structures, but is probably never quite equal to that of the onward impulse of the same column of blood.

In conclusion, it may be remarked that as those impediments which limit the rate of the discharge of blood from the arterial system constitute the first and essential cause of all the subsequent phenomena, so the uses served in the body by the existence of these peculiar

physical effects are, with them, clearly referrible to the same apparent imperfection in the mechanism of the circulation.

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

(For the Medical Gazette.)

[Continued from p. 409.]

Puerperal Insanity.

SPEAKING of puerperal insanity, in the Library of Practical Medicine, Dr. Prichard observes, that "the disease is one of indirect debility, and is perhaps analogous, in some of its pathological conditions, to instances of delirium tremens, or delirium traumaticum, and to some forms of febrile delirium—those, namely, in which the pulse is weak, and small, and rapid, and the skin relaxed. A moderate and judicious use of stimuli, and especially of wine, is, in these instances, productive of the greatest advantages, whilst an opposite method almost certainly leads to a calamitous result."

I know no better ground than that afforded by the above description of an important disease, for an enumeration of *ordinary* cases, such as I promised at the outset of these contributions, not as exceptions, but as illustrations, of the disease or general head under which they fall. The pathological and therapeutical principles laid down, as above, by Dr. Prichard, I believe to be of great general truth. On the other hand, I believe that the cases of puerperal insanity which I shall proceed to describe are not unfrequent forms of the disorder, and that the practice pursued in them has no peculiar feature constituting it an exception to the ordinary rules of practice. And yet I may fairly affirm, that the description quoted above, from Dr. Prichard, would not afford any clue to the conception either of those cases or of that practice. The principle involved in it is thus not valueless only, but even dangerous, unless contemplated in immediate reference to actual cases.

I may be answered, that experience will supply us with distinctions as to the varieties of treatment and disease

falling under general heads. This is most true; but the younger members of the profession must be well aware that hospitals and dispensaries are not always within their reach, and that private practice arrives slowly. Therein consists the advantage of that enumeration of ordinary cases to which I have above adverted, as subsidiary to the slow growth of personal experience.

Mary Ann Saunders, æt. 27, admitted into the Infirmary of St. Marylebone June 2d, 1841, had been delivered of a healthy infant three weeks before. She was a strong, well-made person, of a fair complexion. Her lochia had been deficient; delirium came on at the end of a week after her confinement, and had then been quieted by large doses of the Liq. Opii Sedativus. Lately I understand that she has been much purged. She is now incoherent and excited.

Sumat Ammonise Sesquicarbon. gr. vj.;
Confect. Aromat. gr. x.; Misturæ
Camphoræ, ʒiiss. 6tis horis.

5th.—Less violent; she takes her food (milk diet) freely. Sleeps calmly; breathes quietly; pulse sharp, 100; offensive greenish discharge from vagina.

Perstet.—Sumat. Hyd. c. Cretâ, gr. v.
8vis horis.

7th.—Pulse reduced to 80, softer; tongue more moist, clean; bowels gently open; sleeps quietly; she is more rational.

10th.—She was restless last night; the bowels full, not flatulent; urine scanty; her manner dull—towards evening it became restless.

In the morning, I ordered that the powder be continued, with one grain of squills, and the previous mixture. In the evening, there being pyrexia, with a sharp pulse, Cucurb. Cruentæ ad ʒvj.; Liqueur. Opii Sedativ. ℥i xxv.; Lotio frigida capiti.

12th.—She was much relieved by the Cucurb. &c.; did not sleep much, but more than the preceding night; pulse quick, not sharp; tongue dryish; bowels very open; urine increased.

Pil. Hydrarg. Pulv. Ipecac. co. aa. gr. iiss.
6tis. Tinct. Hyoscyam. ʒss.; Mist.
Camph. ʒj. 8vis.

13th.—Much more coherent; has to-day twice had voluntary motions, having recently passed them without calling for assistance.—Perstet.

15th.—The tongue was clean, and she had been relieved by an aperient draught this morning. Urine also had passed after 24 hours' intermission; but the pulse was quick and sharp.

Cucurb. Cruentæ Nuchæ ad ʒviij. Pil. Hyd. Chlor. Co. gr. iij.; Morph. Muriat. gr. ʒ 8vis.

17th.—Pulse still sharp; motions voluntary; but abdomen tense; refusal to take food, and extreme waywardness and incoherency.

Emplast. Lyttæ capiti raso; Pil. ut supra bis quotidie.

18th.—Haust. Aperitiv. ex Ol. Terebinth. ʒiij. statim.

ʒ Hydrarg. Chlorid. gr. ij. 6tis.

19th.—Abdomen flaccid and soft to-day. Pulse soft. Motions copious, and again uncontrolled. Tongue red and dry. She is quiet, but cannot answer questions. She has had, and is taking,

Mist. Ætheris Co. ʒiss. 8vis.

20th.—She is better, and has slept tolerably; pulse quiet; skin cool; face composed; belly soft; bowels open; urine plentiful.—Perstet.

22d.—Hyd. Chlorid. gr. ij. bis quotidie.

23d.—Ptyalism moderate: from this time she became, and continued, much better, to

July 3d, when she was suddenly violent; her pulse 90, and sharp; tongue clean but dry; head very hot. The bowels were open; no mercury had been taken since the 23d.

Hyd. Chlorid. gr. v. statim. Hirudines, viij. vertici.

6th.—She had been much relieved by the leeches; pulse still sharp; violent perspirations.

During the remainder of this month, she continued free from febrile symptoms, or sharpness of pulse; and she seemed generally to understand what was addressed to her, but made no reply. One commencing exacerbation was checked by

Hydrarg. Chlorid. gr. v.; Opü. gr. j.

She was now allowed three ounces of meat daily.

August 2d. — Baln. pluviale quotid. Haust. effervescentes ter.

13th.—The shower-bath has agreed well. For the first time to-day she

has answered some questions naturally and with readiness. Pulse quiet. Skin very cool. She complains of some headache.

Coffee and two eggs, instead of meat.

19th.—This morning she has been irritable since the shower-bath.

Let it be left off.

28th.—Irritable, and disposed to turbulence.

Sumat Pulv. rad. Ipecac. gr. iv. 8vis.

September 1st.—Not nauseated by the powders; still rather turbulent. Pulse low; off her food; but tongue clean.

Let her resume the shower-bath and leave off the powders.

5th.—Quiet, but also very dull. Pulse low.

Sumat Træ. Ferri Ammoniat. ʒxxv.; Vin. Ipecac. ʒxxv. e Mist. Camphoræ, 8vis.; Pil. Colocynth. Co. p. r. n.

16th.—Much better.

She was discharged as well, October 2d. But her temper was wayward; and her catamenia had not yet returned.

Mary Roberts, æt. 34, October 24th, 1841, of good previous health, full, fair person, was confined a fortnight ago, nursed her infant, which has been recently removed on account of her violence; does not seem to miss it; wanders, and runs on incoherently, calling herself the Virgin Mary. She has been insane after a former confinement; and then was at an asylum. The lochia are trilling in quantity.

Sumat Mist. Camph. ʒxj.; Træ. Humuli, ʒss.; Liqueur. Opü Sedat. ʒlv.; Potassæ Bicarbonat. ʒss. 6tis.; Ol. Ricini, cost. med. j. cras mane.

25th.—Bowels have been freely opened. She is very restless and irritable, but has no sharpness of pulse.

Pt. in usu Haust. Pil. Calomel c. Morphisæ Muriat. o. n. Diet two eggs, and beef-tea.

26th.—Sleepless during last night; eye glistening; delirium violent; bowels open. Both pill and mixture have been refused.

Suppositorium ex Opü grs. iij.; Sapon. Hispan. q. s. inserend.

27th.—The suppositorium had been retained; she has slept well for two hours, and is much quieter; has taken

some arrow root, having recently refused all food.

Repetatur suppositorium nocte si sit opus.

28th.—An enema terebinthinæ, ʒj., was ordered this morning, the night having been restless, and the motions dark, offensive, and scanty.

29th.—A good night after the enema, seven hours sleep; very large evacuations; the pulse soft; she is quiet, takes food, and looks better.

Another enema on the 30th produced little effect, and no benefit. Much turbulence, without flushing or action of pulse.

Liquor. Opii Sedativ. ℥xxx., were given ineffectually on the night of the 31st, and five grains of calomel equally so, in respect to her turbulence, on the night of November the 1st, though this latter dose relieved the bowels freely of dark feces.

November 2d.—Dulness, and in the course of the day stupor took the place of turbulence. In this state she was cupped ad ʒviij., and finally was roused from it by sinapisms after some hours. The bowels were open, but for twenty-four hours no urine was made.

Samai Hyd. Chlorid. gr. ss.; Ext. Conii gr. iij. 6tis. Pil. Colocynth. C. p. r. n.

6th.—Moderate pytalism, with remission of all her symptoms.

From this time to the 20th of November, when my notes of the case cease, she continued free from exacerbation; and though sometimes incoherent, both able and willing to answer questions. The improvement here noticed was certainly most obvious while she was under the influence of the mercury, particularly in relation to her temper. Her physical health improved in an equal degree.

The ultimate prospects of this case were not as favourable as those of the first one. Strong predisposition had been shewn in the repetition of the disorder.

In both these cases, it will be observed, that improvement of a marked kind was contemporaneous with moderate pytalism.

[To be continued.]

REPORT

ON THE

ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from p. 399.]

DURING the year 1840, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2173 women—Of which cases,

27 were twins—being one in every 80½ cases: of these in 11 both heads presented; in 14 the presentations were head and breech, or some part of the inferior extremities; in 2 both were breech or inferior extremities. In 11 of these cases both children were boys; in 7 both girls; and in 9 of different sexes.

1144 were males.

1056 were females.

2131 were presentations of some part of the head, of which 9 were face presentations—about one in every 244½ births.

60 were presentations of the breech, or some part of the inferior extremities—about 1 in every 36½ births; of these 18 were twins.

9 were transverse presentations—about 1 in every 244½ births; all were at full time, except 1 at 7½ months; all were delivered by "turning;" 4 were living; 5 still-born. One was the woman's third child; and all she had borne presented transversely.

In 10 the placenta was implanted over the os uteri; 6 entirely; 4 partially—one in every 220 cases. All the women were delivered by "turning;" except two, in whom the placenta was only partially covering the mouth; one of these was delivered naturally five hours after the membranes were ruptured designedly; the flooding ceased on the escape of the waters, and the woman did well. In the other case, as the hæmorrhage continued after the membranes were broken, when the head had descended sufficiently low, the forceps was applied. The woman never rallied, and died within an hour and a half. Another woman also died in an hour and a half after delivery. Another on the fourth day; and another,

who was delivered at 7 months, on the thirteenth day. All these women lost a large quantity of blood; and not one of the children was saved.

10 were complicated with alarming hæmorrhage before delivery, not the result of placental presentation—one in every 220 cases. All these women were delivered naturally; the hæmorrhage being controlled by the rupture of the membranes. Three of the children were born alive; seven dead. All the women did well.

In 9 the placenta was retained within the uterus, either by atony, or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—about one in every 244 cases. With all these there was considerable hæmorrhage. One was a case of twins. One was a shoulder presentation at 7 months. Two of the women died; one five weeks after delivery, of irritative fever, the effects of the loss of blood; the other in 11 days; there was a large polypus within the uterus, which sloughed off after labour; under the irritation consequent upon which process she sank.

4 were delivered by craniotomy—about one in every 543 cases; they were all first labours, and in all the cases the pelvis was contracted in its dimensions; in three at the brim; in one at the outlet and cavity. In one the funis prolapsed. Where the pelvis was contracted at its outlet the head was strongly impacted, and the child was putrid. All the women did well.

6 were delivered by the forceps; two by the long, and four by the short instrument—about one in every 362 cases. One of these cases was a partial placental presentation; the child was still-born, and the woman died in an hour and a half. Another woman died in a week from hysteritis. Where the long forceps was used, in both the cases the pelvis was contracted at the brim; in neither could an ear be felt; in each the face was looking towards the right groin; both were primary labours; both the children were born living; and both the women did well. Besides the child mentioned above, three others were still born.

1 was complicated with convulsions after delivery. It was the woman's first child. She was in active labour about seven hours, during which time

she suffered greatly from sickness and drowsiness, with some "snoring" between the pains; but she did not complain of headache, and was perfectly sensible. She continued quite sensible to every thing around her for six hours after the birth of the child, when she suddenly went into a convulsive fit. She was speedily bled largely, and had leeches applied to the temples. She remained, however, quite insensible, and the fits recurred both frequently and with great violence; altogether she had had twenty-four when I first saw her, about ten hours from the attack. She was then perfectly unconscious, rolling about the bed, and moaning distressingly. She was again bled to about 25 ounces; this second bleeding put a stop to the fits, and she had none after. She continued in the same state of insensibility, however, for twelve hours longer, when she began to recover her consciousness, and it returned gradually. She eventually got quite well. When I saw her for the first time, after her sensibility returned, she told me she was quite sure the child was not her's, because she had had no pain; and although she had appeared perfectly conscious to every thing that had happened during the whole of her labour, and for six hours after, yet she recollected nothing of it, and had only a faint remembrance of the midwife being fetched, which was more than fifteen hours before the first fit occurred. I have remarked, on many other occasions of recovery after puerperal convulsions, the same obliviousness in regard to events that had occurred many hours previous to the attack, at a time when the patient appeared to have perfect possession of all her mental faculties. For a striking case of this kind I would refer to my work on the Principles of Obstetric Medicine and Surgery, p. 584, note.

8 women died either within the puerperal month, or from puerperal causes—one in every 271½ cases; 7 only, however, as a consequence of labour, for one woman died from the effects of a sloughing polypus—being one in about every 310 cases.

2120 children were born living.

80 children were born still—one in every 27½ births.

Of the Deaths,

4 were from the effects of hæmor-

rhage under placental presentation; one an hour and a half after delivery by "turning;" one an hour and a half after delivery by the forceps—a partial placental presentation; one on the 4th, and the other on the 13th day after delivery by "turning."

1 a week after delivery by the forceps, from hysteritis.

1 from peritonitis, on the 5th day after delivery.

1 from fever, 5 weeks after delivery; there had been an adherent placenta and great hæmorrhage.

1 from the effects of a sloughing polypus of large size within the uterus, on the 11th day after labour; there had also been an adherent placenta.

Of the still-born children,

10 were premature; 1 was a placental presentation.

14 were putrid, at full time, or nearly so.

8 were breech presentations, at full time, or nearly so; two of these were twins.

5 were transverse presentations.

With 8 the funis prolapsed by the side of the head; in one other case of prolapsed funis the child was born living. The funis also prolapsed by the side of the breech in three cases; all the children were born dead, and in one shoulder case; this child was delivered by "turning," and born living.

With 1 the funis was five times coiled around the neck.

1 was a face case.

4 were delivered by craniotomy.

2 were delivered by the forceps; besides the case of partial placental presentation.

9 under placental presentation; 3 of these were partial; 1 was delivered by the forceps.

6 under dangerous accidental hæmorrhage; another was born still after accidental hæmorrhage, but being putrid it is classed with those above.

2 were under very lingering labours.

3 were born after the mothers had suffered from accident or alarm.

1 was monstrous. The mother was dropsical.

1 had universal dropsy. The woman always became dropsical when pregnant, and this was the third dropsical child she had had. There was an immense quantity of liquor amnii, and an enormously large placenta.

5 were at full time, or nearly so, not putrid, nor delivered by art; there being no assignable cause for the calamity. One was a first child of twins.

DISLOCATION OF THE METATARSUS.

To the Editor of the Medical Gazette.

SIR,

THE insertion of the following case of a rare dislocation, in your valuable periodical, will oblige your constant reader,

JAMES KIRK, M.C.

405, Gallowgate, Glasgow,
May 30th, 1844.

In the month of May last, I was called in a hurry to a mill in the neighbourhood, to see a woman who was said to have her foot out of joint; and on arriving found this to be actually the case; the patient, a pale, thin, middle-aged woman, having suffered a partial dislocation of the metatarsus from the tarsus. The metatarsus was driven inwards, and formed a projection to the extent of an inch on the inside of the foot, and left a corresponding depression on the outside.

The reduction, which was easily accomplished, was effected by grasping the tarsus in one hand, and the metatarsus in the other, and pulling or pressing in the direction calculated to bring the articulating surfaces into apposition with one another. A bandage was then applied to the foot, and the patient was sent home. On visiting her next day, at her own house, the foot was found to be so much swelled, and so painful, that the bandage could not be borne; it was removed, and an evaporating lotion substituted; the patient was desired to lie on her back, and to keep her foot straight by means of a pillow placed on each side of the limb.

Five days afterwards, the swelling, heat, and ecchymosis, having disappeared, the bandage was reapplied, and the patient was allowed to sit up; but was instructed to be very cautious in using the foot.

As might be expected, this woman was confined to the house, and walked lame for a considerable time afterwards.

CASE OF
OLD STRICTURE IN THE URETHRA,
SUCCESSFULLY OPERATED ON BY THE
LANCETTED STILETTE.

To the Editor of the Medical Gazette.

SIR,

By inserting the following case of old stricture in the urethra, successfully, operated on by the lancetted stilette, you will oblige,

Your obedient servant,
J. M. WALKER.

Newcastle-on-Tyne, May 22d, 1844.

J. R. W. aged 56, has had strictures in the urethra for twenty years, and for the last four has passed his urine, at various times, from four fistulous openings in the perineum; has had nothing done for four years, except once when the gentleman he was under attempted to pass a bougie for him without success. He has partial paralysis of the right side, of recent date, and his general health, for some time, has been so bad as to preclude any treatment by bougies. I proposed to him, in consequence of the miserable condition he was in, being obliged to leave his bed as often as ten times in a night, to perforate the stricture; and on the 3d of May last, in the presence of Mr. Heath, one of the Infirmary surgeons, and my friend Mr. Miller, of this town, I proceeded in the following manner:—

The straight armed catheter, of the fashion and make recommended by Mr. Stafford, was introduced up to the stricture, which was two inches from the orifice, and from that point, for five inches, the urethra was felt as a hard cartilaginous mass; the stilette was pushed on until we obtained six inches and a half from the orifice; it was then agreed not to proceed any further that day.

On the 6th the armed curved catheter was introduced as far as we had proceeded before. Adhesions were found to have formed, but they were easily overcome. After pushing on the stilette for one inch, we again decided to rest a day.

On the 8th the same instrument was introduced up to the point we left off at on the 6th, and after a little difficulty I felt the instrument begin to glide smoothly on towards the bladder. The instrument was left in for two hours, after which time, when I called, ob-

serving the urine escaping past the instrument, I removed it. Its withdrawal was followed by a full stream, which, however, soon failed and stopped; I then introduced a catheter, and removed the remaining urine. Considerable uneasiness is felt at the seat of the prostate when the catheter is introduced, so much so as to prevent the instrument from being retained for any length of time; but as I soon found that it was only necessary to go beyond the fistulous opening to obtain all that seemed desirable, I now used a straight catheter passed up to that point, and the urine escapes freely through it. The remaining fistulous opening will now have a chance of healing.

The operation thus performed, I believe to be unquestionably safe; I found it extremely easy of performance.—Should a similar case present itself again, I should prefer using for it the straight instrument only; and probably a stilette differently constructed, by having another cutting blade in the opposite direction, so as to make a crucial incision, which would enable the catheter or bougie to pass more easily.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

The Causes, Nature, Diagnosis, and Treatment of Acute Hydrocephalus. —An Essay to which the Medical Society of London awarded the Fothergillian Gold Medal for 1842.
By JAMES RISDON BENNETT, M.D.
&c. &c.

PRIZE essays are often very useful books. He who carries off the palm, has commonly enough, in these days especially, more than one competitor, so that his work may fairly be looked on as the best sample which the world of intellect can produce at the time. The prize itself is always small; the honour of winning it is proportionally great. The price paid is nothing; the praise that follows success is all: and “ambition,” a term which, in connection with matters medical, we assume to mean “a desire of honourable distinction among our fellows,” we are assured, on high authority, is “the last infirmity of noble minds.” Persuaded that all works to ultimate good in this

world of ours, we look on the Fothergillian prize, and the Jacksonian prize as endowments creditable to their founders, convenient as giving to the rising members of our profession a fair opportunity for trying a flight by themselves; and when they prove the means of eliciting such publications as that the title of which heads this article, instrumental in adding another to our list of good books, and a good book is the best and highest bequest that man can leave the world in which he has lived, and by way of making some return for the modicum of good it has done him during his life.

The competitors for prizes are commonly somewhat young men, and now that we have passed our grand climacteric—alas that we should have to say so!—we own that the books of our younger brethren rarely satisfy us, rarely suit our ancient palate. There is a greenness, a necessary immaturity about the work of a young medical author, that impresses the older and more cultivated sense unfavourably. In perusing Dr. Bennett's work, we escape this setting of the teeth on edge; we find that we have the production of a man who has attained to maturity of judgment along with maturity of years. This Essay on Acute Hydrocephalus is not written for the nonce, and with the peculiar purpose, as it were, of winning the Fothergillian gold medal. Attached for many years to one of the largest and most liberally endowed of our metropolitan dispensaries, where the opportunities of seeing and studying disease are all but unlimited, Dr. Bennett had had his mind directed to the subject of hydrocephalus long before it was proposed as the theme of any prize essay; and he may be said rather to have come out under the aegis of the Fothergillian medal than to be its progeny, its consequence or effect. The gage he has won is but the Waterloo medal at the button-hole of the veteran already distinguished in arms before he beat Napoleon at La Haye Sainte. We have the work some few years probably before it would otherwise have appeared, because the Medical Society of London proposed its subject for their Fothergillian prize, and we are glad that they did so, seeing the fruit which that proposition has borne.

Dr. Bennett divides his work into seven chapters. In the 1st, he de-

scribes the general characters and varieties of acute hydrocephalus, the progress and the order of its symptoms. Here he distinguishes a gradual and an insidious, a frankly inflammatory or febrile, and a secondary or consecutive form of the disease. Under this head he also discusses what has been called hydrocephaloid disease, but which Dr. Bennett designates not inappropriately as pseudo-hydrocephalus, an important form of malady with which all who have practised among the poor children of the metropolis must be perfectly familiar.

In his 2d chapter, our author gives the statistics of acute hydrocephalus, and here finds opportunity to pay a well-merited tribute to the labours of Mr. Farr in the Registrar-General's department—Mr. Farr, who is an honour to our profession, and who has made Europe his debtor for the science and method he has displayed in all that has been committed to his charge in one of the most important branches of politico-economical science now cultivated. From Mr. Farr's tables, it appears that of 566,394 deaths from ascertained causes which occurred in the course of 1838 and 1839, 15421 were from hydrocephalus, which is at the rate of 1 in 37·384 of the mortality; and if the mortality among young subjects from hydrocephalus be contrasted with the mortality from other known formidable diseases of early life, such as measles, hooping-cough, scarlet-fever, &c., it will be found that it is on an average of years equal to almost any of them; probably, were all the cases that might be truly referred to hydrocephalus strictly reckoned, it would be discovered to be the most fatal of all the diseases of infancy. The most prominent feature in any fatal disease is very commonly assumed as a means of designating it; and as convulsions are extremely frequent in hydrocephalus, and we find that in the year 1839, 2911 children are set down as having died of convulsions, we are quite sure that a certain proportion of these convulsive cases were genuine hydrocephalus. Were we to add one-fourth of the fatal convulsive cases to those happening from cephalitis and hydrocephalus, we should have 2005 deaths from this peculiar affection of the brain, which is 583 more than the 1422 deaths which occurred from measles—the disease most

fatal to infancy in the course of that year. This is enough to show the very formidable nature of hydrocephalus, and the great mortality that accrues from it. The influences of season and of sex are next inquired into. Dr. Bennett is of opinion that meteorological peculiarities have considerable influence in inducing the disease. He has seldom observed that cases of hydrocephalus occurred singly. We can add our own testimony, from very ample observation, to the same point. We have, at one of our metropolitan charities, sometimes seen nothing of the disease for several weeks, and then we have had five and six cases under our care at the same time. The disease would even appear occasionally to assume an epidemical form. The disease is probably of equal frequency in the two sexes. The age at which it occurs most commonly appears to be from the fifth to the seventh year; under the seventh year it is much more common than at any other period of life—of 155 cases, 99 were in subjects under seven years of age.

In his 3d chapter, Dr. Bennett discusses the morbid anatomy of acute hydrocephalus. Sometimes no morbid appearance is left beyond the presence of a little limpid water within the ventricles and under the arachnoid, and Dr. Bennett concludes that this serum is no evidence of inflammation. Another very frequent appearance is a certain softness of the general substance of the brain, or of its central white parts. There is considerable difference in the minds of practitioners as to the pathological import of this white softening; our author is indisposed to side with those who see nothing in organic changes save such as have been caused by inflammation; and inasmuch as the change in question is often conjoined with diseases of acknowledged debility, he cannot make up his mind to regard the soft state of the brain in hydrocephalus as necessarily indicative of pre-existing inflammation.

Dr. Bennett, however, admits with the majority of recent writers on hydrocephalus, that there is very frequently inflammation of the membranes, particularly of the base of the brain. Our own experience confirms Dr. Bennett in the accuracy of this conclusion, and in the stress he is disposed to lay on

the granular appearance of the serous surfaces, in consequence of the deposition of lymph in the form of minute grains.

Dr. Bennett's 4th chapter is on the ætiology of hydrocephalus. It is easy to name certain causes which should predispose to hydrocephalus in early life; but it is still extremely difficult to imagine why these should operate so forcibly in single instances, only or in particular families, and not generally.

The 5th chapter is devoted to the consideration of the *pathogeny* of hydrocephalus. This is a new word for the *causa proxima* of a disease. Here we find Dr. Bennett's views in very precise terms, and in few words; his conclusions are:—"That vital changes in the brain, chiefly in the central white parts, of the character probably of tubercular degeneration, are the primary causes of the simple forms of hydrocephalus; and that softening, effusion into the ventricles, and meningitis, are all consequences of antecedent alterations of nutrition." These conclusions are qualified to a certain extent afterwards, but they are evidently those which have been forced upon the author by his own observation, and we think them so near the truth, that we shall not lessen their force by quoting farther from this section.

The 6th chapter is on Diagnosis, and the 7th on the important subject of Treatment.

In the truly acute inflammatory forms, Dr. Bennett advocates the abstraction of blood generally and locally, free purging, cold to the head, and all the other elements in the antiphlogistic plan. There can be no question of the propriety of this practice; and we can say as much for all the other particular instructions which our author gives both as to remedies and prophylactics. To quote all excellent that is said on these topics would be to quote Dr. Bennett's concluding chapter entire. This we shall not do, but beg to refer both our older and our younger readers to the work itself for a summary under the guidance of ample experience of everything that is known both of the nature and cure of the interesting disease of which it treats. In conclusion, we add that the work is carefully and even elegantly written; just as the work of a scholar and a physician ought

to be; and that in point of typography and paper it is unexceptionable; the printer has done his part almost as well as the author.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

THE MEDICAL PROFESSION, AND THE ESTIMATION IN WHICH IT IS HELD BY THE PUBLIC.

WE have the following letter from an esteemed correspondent, and adopt it as containing matter that must be interesting to a large body of our readers.

MR. EDITOR,

Your leading article last week contained some remarks on the loss of public estimation which our profession has experienced of late years. I conceive that, independently of some instances to which you allude of individual misconduct or unworthiness in parties who ought to have set a very different example, the superabundance in the numbers of the profession, and the consequent excessive competition for the public preference, are sufficient to account for the diminished estimation in which the profession is held. The very fact of Boards of Guardians assembling all over the kingdom to scrutinize, to discuss, and to decide upon the amount of remuneration to be doled out for the services of professional men, has assimilated, in the vulgar minds which predominate at Boards of Guardians, the very humble remuneration which medical men are willing and eager to obtain, with the quality of service which they give in return:—"What you are so eager to give for almost nothing cannot be worth much." Such is the reasoning; such the conclusion. It appears that, in Marylebone parish, the managers of the poor have even repudiated the gratuitous services of the physicians and surgeons, on account of the ex-

pense of the drugs, and the extra allowances in diet which they have been in the habit of ordering for the patients. The Board would be better satisfied to have no medical attendant except the resident surgeon at the infirmary, who being dependent upon the Board for his own subsistence, would not be likely to make them feel the expense of too liberal an allowance of extras for the poor patients. Yet it is not many years since the late Dr. Hooper enjoyed a considerable salary as physician to the Marylebone Infirmary. What has given rise to this remarkable change in the public mind but the too eager competition of the too numerous profession?

In the same spirit which actuates the managers of the poor in Marylebone, a member of an agricultural Board of Guardians has proposed a reduction of the salary of the medical officers, supporting his proposal by saying, "there are plenty of medical men who will be glad to do the duty for any sum, however small; they get so much *learning and genius* from practising among the poor, that they are glad to do it for almost nothing."

I am not a Union surgeon, but I feel that it is a degradation to the profession, and to every member of it, to have its claims placed at the disposal of bodies of men of the stamp of those constituting the majority of Boards of Guardians.

I would suggest to the heads of the profession in London, who may have influence with the legislature, that the remuneration to be allotted to the medical officers of parishes should be settled by the Poor Law Commissioners, that the Boards of Guardians should be allowed to select the medical officers, that when once appointed the due and effectual performance of their duties should be strictly exacted from them, and that they should be liable to be dismissed, not by the Board of Guardians, but by the Commissioners, upon neglect of duty proved against them.

I am, Mr. Editor,

Your obedient servant,

June 22d, 1844.

Our friend certainly hits the nail on the head here. But for the competition among medical men, on the resignation of Dr. Hooper, the physician or phy-

sicians to the Marylebone Infirmary would still have been in the receipt of a respectable salary; we are credibly informed that some among the Board of Guardians, (not the Vestry, as we said in our former article) do not understand how any set of men should be found willing to work for nothing: "I cannot afford to give away my wares, or to spend my time in other people's service for nothing; how should these physicians and surgeons, if they have to live by their profession, be in a different condition from myself? depend upon it they have something out of this which the Board do not understand; indirectly if not directly you may be certain that we pay." And this is the unalterable persuasion, we are assured, of more than one respectable member of the Marylebone Board of Guardians. Marylebone is perhaps the wealthiest parish in the world, and ought to pay its medical officers for their necessary attendance upon the sick poor; just as no medical man ought to be found willing to undertake the responsible duty of attending the poor of a wealthy community without fair reward. We are certain, as we said before, that neither barrister nor solicitor could be found willing to transact the legal business of the parish without remuneration. There is a chaplain, we presume, attached to the Marylebone Workhouse and Infirmary; does he do his office for nothing? The poor die in the Marylebone Workhouse and Infirmary as they die everywhere: are not the dues upon the funeral service regularly paid from the parochial funds to the officiating clergyman?

We have one, and only one, consistent, independent friend in the profession. In the public service, and in circumstances which lay him open to numerous demands upon his time and professional attention, he steadily refuses all who have not a *right* to his services:

all and sundry in the grade of "dependent," he refers to 'the respectable practitioner over the way,' whose house is conspicuously indicated by the red and blue bottles;" "relatives" and "friends" he recommends to "their attendants in ordinary," and if that does not satisfy, he immediately throws in Dr. Chambers or Sir Benjamin Brodie. And this gentleman is a thousand times more respectable, ay and respected too, than if he were at the beck and call of every Duke, Earl, Marquis and Lord, with whom his position brings him into contact.

THE RECTUM INFIRMARY AND ITS FOUNDER AGAIN!

"THE Infirmary for the Relief of Fistula and other Diseases of the Rectum" has changed its name: like a street that had become a scandal from the number of its temples dedicated to the rites of easy Venus, it has been re-baptised: like a rogue and a vagabond, whose old name had become too notorious, it has acquired an *alias*. "The Infirmary for the Relief of Fistula and other Diseases of the Rectum," *alias* "The Charter-House Square Infirmary"! We love the old denomination, however, and shall continue to use it; it was specific; there was no mistaking its purpose. "The Charter-House Square Infirmary" is a blind, a deception; it is a stalking-horse from behind which Mr. Frederick Salmon may shoot twelve other Englishwomen in addition to the twelve he has already dropped into the cesspool of the "Rectum Infirmary." We should have been pleased to have seen him sailing on under his old colours; his success would have continued to be a measure of the gullibility of the public, of its non-indisposition to be dragged through soil-pits, in comparison of which those on the premises of the respectable nightmen who reside beyond King's

Cross and Paddington are pellucid pools of living water. But Mr. Frederick Salmon has carried his point:—

CHARTER-HOUSE SQUARE INFIRMARY:
TESTIMONIAL TO MR. FREDERICK SALMON.

“At a numerous and most influential meeting, convened in consequence of a special requisition, signed by two hundred and seventy of the Governors and Subscribers, addressed to the Right Hon. the Lord Mayor, President of this Charity, and held at the Hall of Commerce, on the 8th ultimo, Major General Sir James Law Lushington, G.C.B., Vice-President, in the Chair: it was moved by Thomas R. Moore, Esq. Surgeon, and seconded by Mr. Alderman Musgrove, Sheriff, and resolved unanimously—

“That the Infirmary for the Relief of Fistula and other Diseases of the Rectum, established in Charter-House Square, having been in existence during a period of about Nine Years, has conferred an important and lasting benefit upon medical science and suffering humanity,”

We deny the fact. The Infirmary for the Diseases of the Rectum we, for our part, esteem a libel upon medical science. Are the public aware of what happened to the daughter of one of the oldest and proudest of the noble families of England in the hands, we believe in the house, of one of these rectum doctors? She had a long and a thick bougie pushed through her bowel into the cavity of her abdomen, and died in due course—as soon, in short, as the symptoms excited by this barbarous usage had time to kill her. Who can this unhappy Thomas R. Moore, Esq. be, who thus lends his name to that which he at least *ought to know* is not the case? He is entitled a surgeon, and must be aware that medical science has gained nothing either from Mr. Frederick Salmon or his Infirmary; nor has suffering humanity derived aught that it would not better and more securely to itself have obtained at any one of our noble metropolitan hos-

pitals, officered as they are by gentlemen of the highest character, most liberal professional attainments, and consummate skill. We, as one organ of the medical profession, as speaking with the voice of all that is respectable in it, utterly repudiate the connection here set up between medical science and the Infirmary for the Relief of Fistula and other Diseases of the Rectum: its very existence we look on as a foul blot on our escutcheon; and all such exhibitions as that which took place on the “8th ultimo” we regard as so many stabs at the honour and respectability of the profession of surgery. It is on this account, and, as we said before, because we feel the duty delegated to us of disclaiming all alliance between either medical science or true charity, and the Infirmary for Fistula, and other diseases of the Rectum, that we raise our voice again in this place to warn the public against quackery and imposition in any shape, and however countenanced.

“It was farther moved by Capt. Sir Edward Parry, R.N., seconded by the Rev. Dr. Vivian, and resolved unanimously—

“That, with the view of recording the opinion entertained of the professional talents and private worth of Mr. Frederick Salmon, and of the services he has rendered to the suffering poor, it is proposed that a subscription be entered into, for the purpose of presenting Mr. Salmon with some testimonial, as a lasting token of their regard, confidence, and esteem.”

Let the 270 requisitionists to the Lord Mayor address themselves privately to the respectable medical gentlemen who attend their wives and families, and ask them in candour what they as professional men think of Mr. Frederick Salmon and the Infirmary for Fistula and other diseases of the Rectum? And let them act upon the answers they receive. If the subscription to

the "Salmon Testimonial" after this amounts to as much as will buy the Founder of the Infirmary for Fistula and other diseases of the Rectum, a brass syringe, or even an old fashioned *vesica armata*—a clyster bag with pipe and items appertaining, which would be the most appropriate present imaginable, and testimony enough of the public estimation—we have no knowledge of the sentiments that actuate the medical profession.

It must surely have been with the rectum-doctors in view, in anticipation of the advent of some of these gentry, or their abettors, that Dante imagined the swamp of human ordure, in which he has plunged certain denizens of his Inferno, and the strange concert performed upon that orifice of the intestinal canal, which is the opposite of the oral aperture, with which the poet and his guide are accompanied on one part of their perilous journey. The poet, it is true, characterizes the *trumpeting* alluded to as "*oscena musica*," obscene music; but what could be so appropriate in connection with the arrival in hell of the wicked Founders and Governors of an "Infirmary for Fistula and other diseases of the Rectum," as a symphony upon the natural instrument indicated? Or might it not even be advantageously made use of in these upper regions? In the account of a dinner, solemnized some few months ago, in behalf of the funds of "the Infirmary," which we have before us, we observe that Mr. Hobbs sings a song "written for the occasion," to the tune, undoubtedly, of "Here's a health to the King, God bless him!" as appears from the last four lines, which are these:

Our Founder length of years attend,
May sorrow ne'er distress him;
For he hath proved the sick man's friend;
Here, here's his health—God bless him!

The next time Mr. Hobbs is required to sing this or any parallel song in Mr.

Frederick Salmon's laudation, we seriously recommend him to contrive the accompaniment we have indicated; it would have a very fine effect, and could not fail to strike from its novelty. Among the 270 requisitionists, there could be no lack of variety of intonation—the lady governesses would of course be selected to supply the trebles, the Lord Mayor and Aldermen could not fail to make first-rate basses.

FUNCTIONS OF THE SPINAL NERVE— ACCESSORIUS WILLISII.

By M. BERNARD.

As general conclusions from his long paper on this subject the author concludes:—

1st. That the spinal accessory cannot be referred to the same type as the spinal nerves at large. The pneumogastric and the spinal do not by any means stand in the same anatomical and physiological relation as the anterior and posterior roots of a spinal nerve.

2nd. The pneumogastric is a mixed nerve which presides over the motory and sensory phenomena of the three grand functions—respiration, circulation, and digestion.

3rd. Among these functions there is one, however, viz. respiration, which participates in the life of volition or relation. This function, therefore, has an additional nerve—the spinal.

4th. The spinal nerve is, therefore, a motor nerve which presides solely over the motions of the larynx and thorax, so often as these parts are employed in phonation, or in any other act that passes the limits of simple respiration.

In other words, the spinal is a nerve of the life of relation appended to the respiratory system, in the same way as the acts over which it presides—the voice, &c. are phenomena annexed to the respiratory act.

The spinal cannot, therefore, be viewed as a respiratory nerve, as a nerve accessory to respiration; it may be said, in fact, always to come into play in opposition to respiration; it is the means by which the accomplishment of this organic function is temporarily prevented; if we would give it a name that should recal its function, it would be necessary to entitle it *antagonistic* or *antirespiratory* nerve.

The spinal with these uses forms an exceptional nerve in the animal economy; and this is not to be wondered at, seeing that it is attached to a function that is itself exceptional, inasmuch as the organs by

which it is accomplished, (larynx, thorax), are by turns within the domain of the life of relation and that of organic life. After the destruction of the spinal nerves, the respiratory apparatus sinks as it were to the level of the merely organic life; the animal become aphonic has no longer any more control over the motions of its larynx, or of its thorax, than it has over those of its heart or its stomach.—*Arch. Gén. de Médecine, Mai 1844.*

TREATMENT OF TYPHOID FEVER.

THE results as to mortality in the hands of different practitioners have been very remarkable. At the Hôtel Dieu, for example, in the service of M. Sandras, the mortality was one in seven; the treatment consisted almost exclusively in the exhibition of small doses of Seidlitz water by way of purgative. At the hôpital Necker the deaths have been but one in twenty, and even one in thirty, if one patient be deducted who came to the house in a desperate condition. The treatment consisted in the employment of emeto-cathartics at the beginning, then purgatives (generally Seidlitz water), repeatedly to the end of the disease; finally, in the exhibition of mild tonics.—*Bulletin générale de Thérapeutique.*

INCONTINENCE OF URINE.

M. CHARRELY recommends the use of the balsams in this troublesome affection. Here are a couple of his prescriptions:—

R Stryax balsam, 6 grammes; Peruvian balsam, 6 grammes; Honey, 90 grammes; Powder of gum arabic q. s. to make an electuary, of which a tea-spoonful is to be taken night and morning.

R Stryax balsam, 6 grammes; Balsam of Tolu, 8 grammes. M. and divide into pills of 30 centigrammes (5 grains), which are to be silvered over and rolled in lycopodium powder. From four to eight of the pills to be taken daily.

The patient is at the same time to make use of tar water by way of tisan.—*Bullet. Méd. de Bordeaux, in Gaz. des Hop. No. 65.*

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Gentlemen admitted Members on Friday, June 21.—W. Gibson.—R. A. Jackson.—H. Deane.—E. Deane.—E. Tegart.—J. T. Perintau.—J. R. M. Lewis.—J. Hughes.—G. L. Shine.

Medicine and the Collateral Sciences.

FRIDAY, JULY 5, 1844.

ON THE
CAUSES OF EPIDEMIC FEVER*
(AFTER DR. ALISON).

BY AN EDITOR.

No man in this country has distinguished himself for enlightened humanity more than the Professor of Medicine in the University of Edinburgh. Since he entered upon life he has not only been at the command of the sick and destitute of his native city in the important matters of personal attendance and purse, but he has been their untiring advocate with the wealthier public and the legislature. He has been foremost in every movement that had their present relief or prospective benefit for its aim. His philanthropy has ever been of the purest kind, and it has still gone hand in hand with economic as well as medical science of the highest order. No wonder that a man so gifted in heart and head should be loved and venerated among his townsmen—that his visits in the abodes of sickness and misery should be hailed as special interpositions of providence to succour and to save! May the new words of charity and wisdom which he has just committed to the press find a response in every gentle mind, and arouse each willing and able intellect to set vigorously to work to find a remedy for the wide spread, and still spreading, evil he lays bare! It is that we may aid Dr. Alison in the sacred cause he has undertaken that we here raise our voice in his behalf, and earnestly beg of our readers to accompany us through these few pages.

We have ourself some experience of disease among the very poor; but they were the very poor of London; and all who read

Dr. Alison's pamphlet, with such experience, will understand the immense difference of meaning that must be attached to the term *very poor*, as it is applied to the most destitute classes of the metropolis, and to the same classes of Edinburgh, Glasgow, and the other larger towns of Scotland. Great as the amount of wretchedness we have been accustomed to witness here, it appears to be absolute affluence in comparison of that which is met with in Scotland. And then we are almost without any idea, in the metropolis, of those formidable febrile epidemics, that seem rather to deserve the name of endemics in reference to the Scottish cities, so constantly do they prevail. If they assume an epidemic character from time to time, it is only because the fire, which has never ceased to smoulder, bursts forth into a blaze that attracts particular attention—the spark which gave it birth had never died.

Of course there is a cause for every physical phenomenon that presents itself. Ague, which was for ages indigenous to England has well nigh disappeared from her soil; we have drained our meadows and our marshes, and so have got rid of its cause. A worse evil has supplanted this old endemic worm; it is *continued fever*, the offspring of destitution, the child, in its turn, of inadequate employment for the population of the country. Dr. Alison makes out this fact clearly, irrefragably, almost with timidity, and fearful that he is going beyond his province of physician, as it seems; but he expresses his conviction of the matter quite decidedly, and quotes facts in support of it that leave no room for doubt. We have, in fact, been too long misled in our inquiries into the nature of fever, and the causes of its production, by hypothetical notions, and the invocation of specific agents, under the titles of malaria and miasm, adequate, as it was believed, to produce certain states of the nervous and circulating systems, to be followed by the

* On the Epidemic Fever of 1843, in Scotland, and its Connection with the Destitute Condition of the Poor. By W. P. Alison, M.D., Professor of the Practice of Medicine in the University of Edinburgh, &c. &c. 8vo. Edinburgh, 1844. pp. 60.

peculiar derangement we designate fever. In looking too far afield for the cause of the evil, we have overlooked it altogether. This pamphlet of Dr. Alison we therefore look upon as a valuable contribution to pathology, though that is not its object. *Destitution*, in other words insufficiency in regard to food, to clothing, and to lodging, is the cause of the fever that has lately ravaged, that still continues to ravage Edinburgh, Greenock, Dundee, and the other manufacturing and trading towns of Scotland. This, medically considered, is a much more satisfactory and intelligible cause than miasm or malaria; economically speaking we fear that it will be much less favourably entertained. When we had to fight against so mysterious a foe as malaria, both medical man and overseer of the poor had a ready excuse for the repeated defeats and disasters they sustained; no one knew precisely how or where to have the enemy; but when he is presented to us hollow-eyed and gaunt-visaged, and we are told that his name is *Want*, we are left no resource save to open our hearts and our hands, and to bid the monster begone.

Epidemic fever is little and rarely known in England. It ravages Scotland as it seems almost incessantly, and Ireland periodically. There can be no question as to the cause which lies at the bottom of this remarkable difference. In England there is ample provision for the destitute poor, who never fall into that prostrate condition of body which makes man obnoxious to all the causes of disease in general, of fever in particular. In Scotland there may literally be said to be no provision whatsoever for the poor, who consequently the moment their own industry fails them, fall at once into absolute want of the merest necessities of existence.

The Scotch abroad are known to be a liberal and an open-hearted people; intelligent, untiringly industrious, if they but live they are necessarily successful in the world,—they have enough for themselves, and something to spare for their poorer or less fortunate neighbours; no men in the world are more generous than the Scottish East Indians. In their own country, however,

their energies are cramped, their powers of making money are restricted, and they are in the same proportion hard and unsympathising—they seem, as a people, to have no bowels of compassion for their poor neighbour. How else can we account for the fact that the Scotchman, domiciled in Scotland has always shown himself insuperably opposed to a legalized provision for the poor?

Dr. Alison, then, evidently feels himself upon delicate ground in urging destitution as the main cause of the endemic fever of Edinburgh, Glasgow, &c. He says, "I have on different occasions adduced evidence to prove—not that destitution is an adequate cause for the *generation* of fever, nor that it is the *sole* cause of its *extension*—but that it is *one* cause of the diffusion of fever." We have no fear of the patrons of the University, or of the Town-Council, or of the Lairdocracy of the "Guid Town" before our eyes, and help Dr. Alison onwards in what we believe to be the right course, by boldly asserting that without the destitution which has long been ascending to Heaven in accents of damnation against the rich in land and in capital of Scotland, there would be no such thing as epidemic fever known. The whole of Dr. Alison's facts and statements give us assurance of this truth. Dr. Alison says well and truly, "Where destitution exists, it prepares victims for fever, but it 'bides its time.' It springs," he proceeds, "from a specific contagion." We will grant that it does, but we add, that whatever grievously assails to depress the powers of life also engenders the disease; fatigue, cold, a wet skin, care and anxiety, confinement, bad air, and last and most effectual of all, *destitution, hunger, the body living on itself*, having nothing to spare. But destitution, hunger, the body living on itself, are synonymous terms, and identical with derangement of function, that is, with disease, call it by what name you will: we call it *fever*.

Disease follows famine as the shadow follows the substance; this is acknowledged on all hands. Look at the following facts, and learn that fever is the disease that in Scotland follows destitution:—

	No. of Men employed by Charity Fund.	No. of Fever Patients admitted.	Average for same month, 1837-38-39
End of February, 1840,	933	74	90
" March, "	556	83	93
" April, "	320	96	77
" May, "	119	133	87
" June, "	35	161	79
" July, "	25	251	70
" August, "	0	392	75

And during almost the whole of August, there were nearly 300, and by the middle of September, above 400 patients, in fever in the Infirmary and Fever Hospital, and from 30 to 50 daily applicants, who could not be

accommodated. On the 5th October, these numbers had increased to 460, accommodated in the hospitals, and 84 applicants who could not be so accommodated.

In February, when there were 933 men employed, there are but 74 patients affected with fever admitted into the hospitals, the average number of cases in former epidemic visitations for the same month having been 90; in August, the benevolent fund is exhausted, no one can now be employed, and the number of wretches in fever is 392! Nor is the evil yet at its height; during the whole of the month of August there are about 300, and by the middle of September 400 patients in fever in the Infirmary and Fever Hospital; and from 30 to 50 daily applicants who cannot be accommodated! Reverting to the causes of this dreadful epidemic, Dr. Alison says he thinks we have unequivocal evidence to show that it is neither due to the air of certain localities inhabited by destitute people, nor to the effluvia of putrescent vegetable and animal substances. He asks, very pertinently, what imposes on those persons who successively fall down in fever, the necessity of living in polluted air? It is "their poverty and not their will consents." All the world knows that the houses in Edinburgh are generally very high; they consist of many, often of six, eight, and ten superimposed stories. There can be no question as to the part of such houses where means of ventilation are most available—it is in the upper parts; but then the poverty of the occupants increases with the relative height at which they live, and poverty intervening, the freer air they either do in fact, or might readily, breathe, goes for nothing. Thus of 47 inhabitants in the two highest flats of a certain tenement, 37 took fever, and 10 escaped; while of 50 inhabitants in the three lower flats only 5 took fever, and 45 escaped. Let medical men abandon the phantom of miasm, and even of contagion, after this, nor seek to escape the sole practical and true, and useful conclusion, to the effect, that destitution and the circumstances it engenders are the cause of the epidemic fever from which the cities of Scotland have suffered so long and so severely. We urge this point the more earnestly, because there is a disposition in the mind of many influential and wealthy persons to escape or overlook it. Malaria, decaying animal and vegetable matters, imperfect sewerage, scanty supplies of water—anything but a scanty supply of food, or of employment, plenty of which is all that industrious Englishmen or Scotchmen or Irishmen require to find themselves in abundance of the necessities of life, and to get beyond the reach of the influences that engender epidemic fever. "There are few places better supplied with water than Glasgow," says Dr. Perry, in his *Facts and Observations*, "and I have observed on more than one occasion that the progress of

malignant fever was rapid and violent during *intense frost*, when the whole liquid substances in the streets were firmly bound together for weeks without the possibility of putrefaction going on." We urge the point of destitution as the grand cause of epidemic fever, we say, from the indisposition which we believe we have recognized in the minds of certain influential individuals to admit it. The people themselves almost universally ascribe their attacks of fever to the privations they have endured. Whilst the unemployed and destitute poor form a small minority, probably not more than 1-20th of the inhabitants of Edinburgh, they nevertheless furnish a very large majority of all the fever cases encountered—usually from three-fifths to two-thirds. In Glasgow it is the same; so it is in Ayr; so everywhere. For instance of 197 patients received into the Glasgow Infirmary, 85 were only partially employed; their earnings were insufficient for their support; and 43 were wholly unemployed, making the total number of destitute 128, against no more than 69 who were attacked with the disease when in full work; and it is quite certain that among these many had undergone unheard-of privations previously to getting into the work, which was probably the immediate exciting cause of their disease: how can the body, taken from starvation, be suddenly compelled upon a course of active exertion, without detriment? It would be necessary to begin by feeding these poor people for a week or ten days before requiring exertion of their emaciated bodies and shrunken veins.

The recent epidemic fever would not appear to have been very fatal in proportion to the numbers it attacked; still, when these numbers are regarded, the total of the victims is found to be very considerable. The fever of 1837 was admitted to have been extremely destructive in Glasgow: it appears that in the course of four months, during the height of that epidemic, there were 972 burials from the Infirmary and Town's Hospital at the public expense; but in the epidemic of 1843, during the four months, January, February, March, and April, there were 848 funerals from the same establishments at the common cost; and how greatly this number exceeds the general average will be seen by comparing it with the number (352) buried during the same months in the preceding year. The number buried at the public charge in 1842 being taken as 1, the number so buried in 1843 will appear to be 2·40—nearly one and a half greater than in the preceding year. But if it be now considered that the deaths from fever amount to about 15 per cent. of the whole mortality, an estimate may be formed of the whole amount of its destructive influence. Nor is

this all; death is not the only evil; one-half of a whole community prostrated by sickness were still a sore calamity! did no one die. The man who is sick is not only incompetent to minister to his own and his family's wants, but he immediately becomes a charge upon others, and hinders them from using their industry profitably—*non est vivere, sed valere, vita*. Now the epidemic of 1843 had a very large proportion of helpless sick for its absolute mortality, different in this respect from other epidemics, though scarcely less disastrous on that account. Nevertheless, see what Dr. Alison says of its destructive power in a single sentence:—

"In three widows' families whom I pointed out to the Royal Commissioners last spring as receiving very inadequate allowances, there have been, since that time, the very unusual number of *five deaths out of eleven children, by fever*." Good God! and this happens in one of the divisions of a country rich beyond all the powers of computation, a country which raises thousands annually to convert the heathen, which sends missions to Otaheite and Peking, and leaves its own little ones to perish for want of bread! Would the reader on this side the Tweed like to know what the allowance to one of these poor widows was? "A woman of delicate habit, who struggled through last winter with three young children on the usual pension allowed by the West Church parish, *fourpence a week for each child, and nothing for herself*." Think of the poor widow and her three children struggling through a winter on the munificent sum of one shilling per week! There are seven days in the week, and twelve pence in a shilling, and four human beings are ruthlessly left to starve on the sum of twelve pence in seven days, which is at the rate of 6·857 farthings per diem for the family, or 1·714 farthing for each individual; and this in a country where bread costs 2d. and meat costs 6d. a pound! Dr. Alison recommended this poor woman for an increased allowance, "but the application was, *as usual, refused*" (p. 15). But see what happened: the epidemic fever appeared; the poor woman herself was the first who took the disease, and two of her children were the first victims. The fever spread, and above sixty inhabitants of the stair in which she and her children dwelt became affected, and eight died. Nor was this all; the fever extended from this tenement to the opposite side of the street, where it committed still greater ravages. One shilling a week might, under certain circumstances, help a poor woman to a far greater extent than those who are accustomed to reckon their income by hundreds or thousands of pounds might imagine; but at the

time the allowance of one shilling per week was made to the widow with her three children there was no work to be had—nothing could be done by which the amount could be increased; what money was obtained over and above the one shilling must have been obtained from casual charity; the poor woman had to descend from her respectability and become a beggar, in order to keep herself and her children from dying of hunger! Did these cruel men who, *as usual*, refused Dr. Alison's petition in the poor woman's behalf, breakfast, dine, and sup upon that day themselves? Did they lie soft and warm at night, and, hearing the wind blow, and the rain patter against their casements, did they hug themselves on their creature-comforts, and thank God for having made them overseers of the West Church parish, and not petitioners before the body for an increase upon an allowance at the rate of 1 farthing and 714 decimal parts of a farthing per diem for subsistence? We trust they did the latter of these acts at all events.

But in Scotland, in Edinburgh especially, the only legal notice taken of all the misery consists in the frequent imprisonment of those who endeavour to procure relief from their sufferings by "the nuisance of street-begging." Our readers will probably remember the instructions issued from the Home-Office to our policemen and constables of the metropolis, not so very long ago, when destitution through want of work was very rife among us, viz. "not to be particularly strict in taking notice of street-beggars." Of course, when the community were starving, it did not answer to put every man, woman, and child who proclaimed the fact by asking alms in the street into prison; for several months last year our prisons would not have held a tithe of the offenders, had the laws against street-begging been strictly enforced; and this in a city where there is ample provision for the poor; where, as the rule, street-beggars are all but invariably persons on the tramp, persons driven from their own homes in the country by the pressure of want, or persons who have obtained a kind of prescriptive right to violate the law, and who make a trade of begging.

Dr. Alison boldly attacks the question as to the causes of destitution. He maintains that the unfortunate condition of the poor of the northern metropolis is by no means generally referable to misconduct of any kind, neither to folly, nor vice, nor intemperance. Besides his own excellent testimony on this matter, which suffices us, he quotes Mr. Johnson, chairman of the committee of the last subscription, who says:—

"During the last five months, I have had

the best means of ascertaining the amount of poverty and destitution amongst the industrious poor of this city; their privations from want of food, clothing, and household furniture, greatly exceed the belief of those who have not the same means of knowing them.

"I have known many instances of *sober and industrious* tradesmen, of all kinds, who, after having sold or pawned every article within their dwellings (their fire-grate not excepted), were driven at last to apply to the committee for a scanty supply of bread or meal to appease the cravings of hunger, many of them urging the plea (which their emaciated appearance too truly confirmed), that for eighteen, twenty-four, or twenty-eight hours, they had not tasted food!

"On all occasions I have found the men most grateful for the smallest pittance, willing to undertake any kind of labour at any price the committee might please to give, and always more thankful for bread and meal, or for money in return for labour, than when given them by way of alms. Their conduct has at all times been characterized by the utmost respect for those interested in their welfare; they were easily reasoned with and guided; and in every instance they frankly and freely communicated their present and past history, which, with very few exceptions, among the thousands of cases tested by the committee, have always proved correct.

"I never knew the bounty of the committee abused by the exchange of rations for spirits, nor that amongst the generality of the unemployed there existed a great anxiety for intoxicating drinks."
 "The cry that drink is the sole cause of distress comes only from those who wish some kind of excuse for withholding their means; it could never come from those who have taken the trouble to investigate its causes."

The truth lies in small compass; it is announced in these few words: "want of work." And is it not one of the saddest among the many sad spectacles we encounter in this world to behold an able-bodied industriously disposed man craving occupation in vain? This was one of the features of human society that appears to have imprinted itself harshly on the mind of Burns, whose writings, like those of Shakespeare, are transcripts of human sympathies, and affections, and feelings:—

"See yonder poor o'erlabour'd wight,
 So abject, mean, and vile,
 Who begs a brother of the earth
 To give him leave to toil;
 And see his lordly fellow-worm
 The poor petition spurn,
 Unmindful though a weeping wife
 And helpless offspring mourn."

The people are willing to work, but there is nothing for them to do. There can be no question, however, in regard to the natural law in reference to such circumstances: every man born into a community has a claim to a subsistence from it; if there be bread in the land he must have his share; he cannot be left to starve. And accordingly, in all the most highly civilized societies in Europe, this right has been recognized; in England, Holland, Flanders, and over the whole of Germany, and, we believe, the North of Europe, *all who are ascertained to be truly destitute have a right to relief*. Truly civilized society can stop at nothing short of this. Yet it is obstinately refused, as we have said, in Scotland; so obstinately, that there is probably nothing for it but the interference of the English portion of the legislature, which must kindly step in, and save Scotland from the sin and crime she is apparently bent on persevering in. To this the legislature ought to be the more disposed, seeing that our friends in the North actually gain nothing by their hard-heartedness. The periodical aggravations of the distress that constantly exists in Edinburgh, and the larger towns of Scotland, have always to be met by the more fortunate members of the community; subscriptions have to be entered into in order that the poor may not actually die of starvation; and the amount of these subscriptions Dr. Alison shews to be fully equal to the sums raised in many of the districts of England in the way of regular assessment for the maintenance of their own poor and destitute. During the last three years the inhabitants of Edinburgh have actually subscribed voluntarily the very large sum of £20,000! but in vain; "all has been ineffectual in preventing an immense accumulation of destitution and misery, and disease consequent thereon." "It is even already obvious," says Dr. Alison in continuation, "that before the end of this year, farther subscriptions for the support of the unemployed poor will become necessary."

The large sum of money mentioned, however, is by no means the free will offering of the Edinburgh community at large, of all and sundry who have something to spare from their own necessary means of present subsistence; it is contributed by some 1200 out of the 150,000 inhabitants of the Scottish capital—the number of persons who subscribed £1 and upwards was no more than 1246! The extraordinary burthen therefore falls on that portion of the community which has already taxed itself most heavily for the support of ordinary charities. These persons, it is to be presumed, are the best able to bear this unusual

burthen; but they ought to be protected in their benevolence, just as the able-bodied, but unemployed, and therefore destitute, poor ought to be protected in their destitution. The cold and unsympathising ought not to feel themselves in a state to transfer their fair proportion of a necessary burthen from their own to their neighbours' shoulders.

The remedy for the lamentable state of things which he shews to exist in Edinburgh Dr. Alison proposes to find in—

1st. Averting "the sin, and scandal, and danger, of unrelieved destitution, by giving, as our neighbours in England, Holland, Flanders, and all over Germany do, a right to relief to all who are ascertained to be truly destitute, from whatever cause their destitution may have arisen. * * * I only add, that this concession of the right of relief naturally involves the *counter right* of inspection, by duly qualified and *responsible* agents, acting on a uniform system, and provided with the means of applying such tests of destitution, and enforcing such checks on fraud or laziness, or on the misapplication of charity, as experience has proved to be effectual.

"2d. We should provide, that the burden thus assumed by the community is laid equitably on its different members; which is to be done, as I apprehend that experience has also shewn, in two ways:—*first*, by the right to relief, in any individual case, being given in that part of the country which has benefitted the most by the labour of the applicant, or of his parents, or nearest connections; and, *secondly*, by the cost of that relief, which is necessary to avert destitution, being defrayed by means of a well-considered assessment."

That is to say, Dr. Alison would extend the provisions of the English poor law in its amended form to Scotland. And he shows by satisfactory statistical documents that this measure, whilst it would not cost the city of Edinburgh more than is now raised by voluntary contributions, would have the immense advantage of reaching all who ought by right, and from their position, to assist—it would be a goad to the lazy brute, and prove a means of sparing the willing horse. The present system of leaving the poor without any sustainable claim to relief, therefore, has nothing on the score of economy to recommend it. Neither has it aught on the side of morality to make its continuance desirable. "It is not," as Dr. Alison very justly observes, "the mere circumstance of being made a pauper, *i. e.* receiving parish relief, which destroys the independence of the recipient; but the circumstance of receiving *any* relief for which no equivalent is given in labour. He who 'of necessity must live by alms' has equally lost his independence, whether he is

made a pauper, or is provided for under one form or another of mendicity."

To those who maintain that the sufferings of the destitute population serve as warnings to others, and answer the beneficial purpose of repressing the growth of a similar population, and therefore ought not to be interfered with, there is this very conclusive answer to be given—that far from having any such effect, experience demonstrates that *the destitute poor unprotected by law multiply much more rapidly than paupers*. In England, with her law which gives to all who are in want and have a settlement, a right to relief, one-fifth of the persons who attain to the marriageable age never marry, and the women, though nubile at seventeen, do not on an average marry till they have attained the age of upwards of twenty-four, nor the men till they have reached that of nearly twenty-five and a half years. But in the most destitute parts of Scotland and in Ireland, in neither of which countries is there any approach to a poor law like that of England, it is familiarly known that one half of all the marriages that are solemnized take place between young persons under the age of twenty-one.

Dr. Alison may be said merely to hint at emigration as a means of relief, and that only in reference to "certain districts hitherto grievously mismanaged." In this we think him right. It has always struck us, that of all the absurd schemes of lightening the burthens of a community, that which made emigration the means was the most absurd. We have long been accustomed to meet the advocates of emigration with the question, Whether a thinly peopled country was ever a rich one? What in fact were the value of the soil if it were not tilled or grazed? what the worth of raw materials without industrious hands to give them fashion? whence would the interest of capital come without profitable employment in the shape of productive labour? What were a country without inhabitants at all? Unfettered liberty to buy in the cheapest market, and to sell in the dearest, is all we ask, is all we require; it were the sufficient panacea for all our social evils, physical as well as moral; for the fevers that cut us down by hundreds, by thousands, and for the bonfires of the produce of our broad acres at which we have toiled through wet and through dry.—But we need not draw upon our own stores when we have such valuable materials as Dr. Alison supplies us withal for a conclusion.

"But if the institutions of this or any other country are such as practically to deny the comforts of life to any considerable part of the community, it must be expected that a generation will spring up, careless of those

comforts, and prodigal of life itself;—degraded in their habits, reckless in their conduct, over whose general mode of life even religious instruction will have little practical effect, because not supported and enforced (as expressly directed in Scripture) by the civilizing influence of human charity. Men brought up in this state of poverty and degradation will live on little, and work for little; they will recommend themselves, sooner or later, more than all other labourers, to that influential class of men, to whom the wages of labour must always appear as so much deduction from the profits of stock; and whose interest, to have labour always available, and at the cheapest possible rate, is opposed to, and ought to be checked by, the interest of the community at large, to have poverty and pauperism equitably distributed, and at the lowest possible amount. Gradually they will supplant all other labourers, or reduce them to a level with themselves; they will have, as all experience shows, the high mortality, and still higher reproductive powers, of the most destitute poor of civilized countries; and while they minister to the wealth of certain possessors of capital, they will overspread the whole country with misery and disease;—they will do for it, in fact, just what a long course of neglect of the poor has done for Ireland and for certain northern districts in Scotland, which have been priding themselves on avoiding assessments, until the number and destitution of their poor have become such, that the argument which they now use against the legal provision is, that to make a decent provision for them would absorb the whole rents of the estates.

“Such degradation of the habits of many poor families, the sure forerunner of a pernicious increase of their numbers, has been, even under my own observation, both a frequent cause and a frequent effect of epidemics of disease in Edinburgh; and to any one who observes and reflects upon its natural consequences, it must appear as a solemn warning, that the sacred injunction on all Christian nations, to “clothe the naked and to feed the hungry,” is not to be trifled with, or explained away; that when one system is found ineffectual for this purpose, another should be tried; and that it is peculiarly incumbent on us, as a nation laying claim to a peculiarly Christian character, to use the faculties which Heaven has given us, to acquire the information, and apply the means, by which the sufferings of the poor, in such a complex state of society as that in which we live, are found to be most effectually and uniformly relieved.”

June 6, 1844.

SKETCH OF THE MENINGITIS
WHICH APPEARED AT GIBRALTAR IN THE
EARLY PART OF 1844.

By DR. GILLKREST,
Deputy Inspector General of Army Hospitals.
(Communicated by Sir J. M'Grigor, Bart.
Director General, Army Medical
Department.)

To the Editor of the Medical Gazette.

SIR,

I HEREWITH forward for your perusal a report on the disease “meningitis,” which has been prevalent among the poorer classes of the civil population in Gibraltar for some time past.

This report appears to me to be worthy of insertion in the MEDICAL GAZETTE.—I am, sir,

Your obedient servant,

J. M'GRIGOR.
Director General,
Army Medical Department.

June 6th, 1844.

During the first six months of 1843, the health of the population of Gibraltar was maintained in its ordinary state; but for several weeks before Christmas, catarrhs (deserving, perhaps, the name of influenza, so often applied in various parts of the world) prevailed, it may be said, epidemically; few individuals or families of any class having escaped attacks of the malady.

The epidemical catarrh having declined, cases of meningitis, possessing very marked symptoms, began to make their appearance about the middle of January; for the most part among young persons of the lower classes; and the disease has since continued to prevail to such an extent, that although the numbers do not warrant my applying the word “epidemic” to it, I still consider it a subject worthy of special notice.

It may be premised that in the course of what we consider here as our “rainy season,” viz. from the beginning of October to the end of March, our supply of rain was unusually scanty; but it cannot be said that in other respects any peculiar atmospheric phenomena were observed. With respect to the drought, it can be stated, that when this has occurred in a similar manner in former years here, it has not been followed by a disease of a similar nature to that which I am now speaking of: so that, as in other instances, we are obliged

to refer the circumstance to certain mysterious atmospheric conditions of which nothing is known, and which must for ever, probably, remain beyond our ken.

Before the setting in, and during the progress of the strongly marked cases of meningitis, it was observed that, in indispositions from any cause, there was a tendency to headache more or less severe; the occiput being, oftener than usual, the seat of the pain; and the muscles of the back of the neck being also frequently affected with aching.

Lest the cases which occurred should only be the advanced guard of a wide-spreading epidemic, I thought it my duty to forward communications to Sir James M'Grigor, from time to time; and the following are to be considered as the substance of my statements upon the subject.

The invasion of the disease was in many instances sudden, while in others certain prodromes existed. In some the commencement of the attack was indicated merely by slight disturbance of the cerebral functions, with a little rigidity of the muscles at the back of the neck, and vomiting; these symptoms perhaps yielded to treatment in two or three days. In many, however, the headache, particularly frontal or occipital, but sometimes general, was most intense from the commencement of the attack; the head being thrown back, and so retained by the rigidity of the muscles, for perhaps several (in some many) days; extreme anxiety and restlessness, for the greater part of the time,—frequently with spasms, or convulsions, or both; pulse not always disturbed in a degree corresponding with the gravity of the other symptoms; injection of the adnatæ, with high febrile movement, only taking place in a very limited number; vomiting and costiveness, in the early period of the attack, have been among the most constant symptoms; and it has been observed, that after the vomiting had ceased for several days, during which the patients seemed likely to do well, this and the other acute symptoms have recurred, followed by a fatal termination. The absence of thirst throughout was among the most remarkable circumstances accompanying the attacks.

In violent attacks, where the symptoms have not yielded to active treat-

ment, or where death has not supervened within a period varying from perhaps the second to the fifth or sixth day, the patients have usually passed into a state of extreme marasmus, in which they have, in some cases, remained for a long period of time,—and from which state, some, to our great surprise, have recovered; while others have ultimately died. These very violent attacks, it ought to be stated, were sometimes ushered in by a severe rigor.

The most striking and general symptom has been the greater or less curvature of the spine, caused by the rigidity of the muscles of the neck; the head in many of the cases was observed nearly to touch the shoulders. In adults, among whom attacks were comparatively few, this symptom existed only in a slight degree, while in some young persons the curvature amounted to opisthotonos.

Along with throwing back of the head, the following symptoms were not unfrequent—strabismus, partial or very perfect, deafness, and amaurotic blindness. In one child of about three years old, and in a state of extreme marasmus for many days, I witnessed all this group of symptoms assembled, and yet it was in its mother's arms, devouring, with avidity, whatever food was put into its mouth, and ultimately recovered.

In two cases, temporary hemiplegia; in three or four, symptoms considered peculiar to apoplexy, and proving fatal, took place. In two, sudden recovery, from symptoms of a very alarming nature, was observed. Somnolency was frequent in the course of the disease. Pupils sometimes dilated, and sometimes contracted; while at other times they have been observed to oscillate. Countenance, in the advanced stage, has sometimes had an unmeaning or fatuous* appearance.

When speaking of the acute stage of very severe cases, it should have been mentioned that the severity of the pain was often indicated by shrieks.

One point, remarkable enough, was, that while, in children and young persons, the thrown back state of the head was a very common symptom, this was comparatively rare in persons more ad-

* The French word, *hébété*, perhaps conveys best what is here meant to be said respecting the expression of countenance.

vanced in life; though, in other respects, the symptoms may have been of the severest nature. It was uncommon to observe that the intellectual faculties remained unimpaired, in the chronic period, to within a short time before death.

Respecting the remedial means employed, there was no difference of opinion whatever; nor could there well be any, where the indications were so obvious. Bleeding, general and local, purgatives, and various derivatives, were mostly relied on; mercury was also employed as soon possible, from its well known property as an "antiplastic," in those diseases where lymph is known to be deposited.

From what I have observed, I quite agree with what has been said by some authors as to the great probability of mischief being caused by cupping, or the application of blisters, or other violent irritants, too near the seat of the inflammation: indeed, I think mischief likely to arise from their application to any part of the body, when the disease is at its height; and upon the same principle, I should hesitate in recommending the application of many leeches near the head under the circumstances mentioned, and especially in young persons, in whom leech-bites often create great irritation.

I agree with those who would prefer, in cases of meningitis, simple irrigation of the head, (the hair being cut close,) to the application of ice, so likely to produce reaction, and a great shock to the system.

Morbid appearances.—As the disease prevailed, with but few exceptions, among the civil population who had been treated in their own dwellings, the examinations were very limited; they were, however, carefully made, and perhaps sufficiently instructive, except in one not unimportant respect: I allude to our being unable to succeed in examining the head of a single case of a child, so as to have it in our power to establish how far, in them, the disease should be considered as the meningitis arising from the strumous granulations of the arachnoid and pia mater, much spoken of by French authors of late years, especially by Dr. Guersent, and respecting which further references will be hereafter made.

Our inspections established, as I believe is always found to be the case in

the disease to which for some years past the term meningitis has been given, that the dura mater was perfectly free from all trace of inflammation.

The arachnoid, if not always opaline in its appearance at its superior portion, with a more or less manifest deposit of lymph underneath, had always the most unequivocal marks of the existence of inflammation at the base of the brain, where even pus (which in a few instances may be said to have been almost in a state of concrete) was usually found.

The pia mater, in the majority of the cases examined, was found remarkably implicated; even traces of pus in its foldings in the sulci of the brain have been observed, and lymph has been found deposited at various points of its spinal prolongation. Some authors seem to be of opinion that this membrane is specially the seat of inflammation in the disease for which the name of meningitis has of late years been adopted.

Though our examinations here have not shewn, in anything like a satisfactory manner, that the inflammation had extended to the substance of the brain, we can hardly conceive, from its close connection with the delicate and very vascular tissue of the pia mater, how this could well be otherwise; and the old name of phrenitis may not therefore, after all, be so inappropriate.

It is now well known how fallible are the rules (at one time so much relied upon) assigning one set of symptoms to certain lesions of the brain itself, and another set to those of its coverings.

The points where lymph or pus, or perhaps both, were found at the base of the brain and lower surface of the cerebellum, in our cases, varied greatly; the deposits on the pyramidal bodies and neighbourhood being perhaps the most remarkable.

The ventricles have, in a certain proportion of our examinations, been the seat of very remarkable appearances: in two cases the quantity of serum thrown out from the lining membrane was so great as to have led us easily to suppose how the term "acute hydrocephalus" may have often obtained in this disease. In these cases a considerable quantity of lymph and pus was found at the bottom of the ventricle, rendering the serum turbid.

Having paid much personal attention to all the phenomena of the above disease, as well as having been in constant communication with the civil practitioners who had most cases, I can confidently offer, as being faithful, the foregoing observations regarding this singular malady, which has prevailed here, through a variety of atmospheric changes, and several days of heavy rain, from about the early part of January to the 20th of May, 1844, on which day a severe case appeared, after an interval of many days without any.

Anxious to obtain all the information possible respecting the diseases to which the town and territory of Gibraltar was liable, I some years ago consulted all the records which it was possible for me to obtain, from the autumn of 1669, when a devastating yellow fever epidemic certainly appears to have prevailed. But the existence here of meningitis, or "phrenitis," in the remarkable manner referred to in the foregoing pages, is nowhere spoken of; the oldest inhabitants are not aware of anything of the kind; and, in the course of my knowledge of Gibraltar for many years, the disease has not occurred in a manner to attract any attention.

Not so, however, with regard to other places; for, as is shewn by Dr. Guersent, in a special and excellent memoir on meningitis, it appears to have prevailed, epidemically, according to various authorities, in different parts of Europe; and he includes among the number one described by Sauvages. He refers to one of very recent date (1839) which took place at Versailles, as described by Dr. Faure Villar, and in which, contrary to what occurred with us here, the military suffered severely; for of 114 attacked (chiefly young soldiers) in one Regiment, 41 died. There is no question of the identity of the symptoms, in our cases, with those described in that epidemic.

As, with us, the majority of the cases occurred between the ages of from 2 and 15 years, the statements regarding the "granular meningitis" written upon by several authors in modern times, and peculiar to young persons, seem to me to be worthy of being referred to. In England, Dr. Green is the last person who has written about it. I mentioned in a former page, my regret at not having been able to verify, by dissec-

tions, how far these morbid deposits, described as taking place in the arachnoid or pia mater of children, and furnishing a source of inflammation (as such strumous granulations in the peritoneum do) may or may not have been a *fons mali* in our cases; but we are prohibited from believing the affirmative from the number taken ill within a certain time (*many* within the same week) having been so great; and the dissections, in *adult subjects*, presented no such deposits.

The memoir of Dr. Guersent, physician to a very large hospital for sick children at Paris, is very interesting upon the form of meningitis having its origin in the tubercular granulations I am now speaking of; and he gives a summary of what has been said most worthy of notice by others; describes the liability of those granulations to remain a considerable time latent, and to cause, at first, a modified and chronic degree of inflammation, producing only symptoms of a very modified and obscure kind; until, arriving at a certain point, the explosion from the setting in of the acute inflammation demonstrates clearly the perilous nature of the disease. It has been attempted to draw distinctions between the acute stage of this form and the simple meningitis, but Dr. Guersent admits that where the violent symptoms set in in both, without antecedents in the one, it is almost impossible to make a distinction.

With regard to the number of cases which occurred within the period already specified, viz. from January to the 20th of May inclusive, a near approach can be made, though the exact numbers cannot be given, as two or three private practitioners, who have had a few cases, have not given in statements.

In our civil population (of about 16,000), 450 may be considered about the number of cases of all grades which occurred; about 190 of that number having had symptoms of more or less gravity; 42 deaths took place.

It was noticed during the period, that there was a very prevalent disposition to headaches among the population generally.

Among the military, though it was observed by some of the medical officers, that during the same period the head seemed to have been particularly affected, two men only died, and one child.

With but very few exceptions this disease prevailed among the indigent classes, and of these the indigent classes of the Portuguese nation (in considerable numbers here), and whose diet is very inferior, were those who were attacked in the greatest number.

The bulk of the cases occurred below the age of 18, and but a very few were attacked with this disease in a very severe form, beyond the age of 30.

In respect to sexes the attacks seemed to have prevailed pretty equally in both.

J. GILLCREST, M.D.

Deputy Inspector General of Army Hospitals.

CASES OF

SPINA-BIFIDA: WITH REMARKS.

By FRANCIS HEWETT, ESQ.

Curator of St. George's Pathological Museum.

(ACCOMPANIED BY A SKETCH.)

(For the *London Medical Gazette*.)

CASE I.—M. A. Smith, a well-developed child, *æt.* five months, was admitted into St. George's Hospital, under the care of Mr. Tatum, for spina-bifida corresponding to the whole of the posterior sacral region. The tumor, of the size of a turkey's egg, was transparent, and the skin covering it was natural, except at the apex, where it was slightly discoloured. There was no paralysis of the inferior extremities; the stools and urine were discharged naturally. The child was also affected, but not to any great degree, with hydrocephalus.

Mr. Tatum punctured the tumor with a grooved needle, and let out 3ij. of transparent fluid; a pad and roller were afterwards applied, so as slightly to compress the tumor. The child did not appear to suffer any inconvenience from the operation, which was repeated in a few days: the head then became smaller. Convulsions subsequently came on, and continued, at different intervals, for several days; the head increased in size; the tumor inflamed; and its walls became somewhat thickened. The operation was, in a few days, repeated, and some blood-tinged fluid was let out. Three days afterwards the patient became very feverish and partially comatose, and an eruption, which turned out to be measles, made its appearance on the body. The child died a few days afterwards.

Sectio cadaveris.

The head presented the appearances commonly observed in hydrocephalic cases; the fluid was in the ventricles of the brain.

The tumor occupied the whole of the posterior surface of the sacrum, all the laminae and spinous processes of the sacral vertebrae being completely deficient. The walls of the tumor were thickened, and the skin was in some parts coriaceous; with this exception, there did not appear to be any well-marked traces of inflammation either about the chord or its membranes. The cavity of the tumor was intersected by the extremity of the chord and the nerves emanating from it. The chord and its nerves, passing out of the spinal canal at the upper part of the opening, ran across the cavity of the tumor to its posterior wall, where they were firmly fixed, the nerves being here flattened and spread out upon a fine membrane. From the sac, the anterior branches of the four first sacral nerves returned in distinct bundles, forming large loops, to their anterior sacral foramina, through which they passed, as usual, to form the sacral plexuses. The extremity of the chord, and the bundle of filaments forming the anterior branch of the first sacral nerve, were, towards the sac, so closely united, that they could not be separated; but towards the sacrum they were about the distance of a line from each other; the two lower anterior sacral nerves did not pass through the cavity of the sac; all the posterior sacral nerves were lost in the coverings of the tumor. The fluid had evidently been effused between the visceral arachnoid and the pia-mater; the serous membrane was widely separated from the spinal marrow and its nerves in the whole length of the canal; but at the opening communicating with the sac the visceral arachnoid had been forced outwards, and was traced to the neck of the sac, where it became so intimately connected with the parietal arachnoid that it could not be separated from it. The walls of the sac were thus formed by the two layers of the arachnoid, by the dura mater, and skin, all of which were much thickened and firmly united to each other.

The connexion of the chord and nerves with the sac is figured in the annexed sketch.

CASE II.—In 1843, I was asked to see a child, *æ*t. 8 months, who was affected with spina-bifida. The tumor, of the size of a large egg, was situated in the lumbar region; the skin was natural, except at the apex, where it presented the appearance of a fine transparent membrane, with some large vessels minutely injected; there was no paralysis of the inferior extremities; the bladder and rectum were not affected. The head had increased very much latterly, and evidently contained a large quantity of fluid.

No surgical treatment beyond that of slightly supporting the tumor by means of a bandage was adopted.

The disease went on gradually increasing; the skin became inflamed, and burst at the centre of the tumor; extensive suppuration of the sac ensued, and the child died.

The parents would consent to the examination of the tumor only.

The aperture communicating with the spinal canal was caused by the deficiency of the right laminae of the middle lumbar vertebrae; the left lamina and the spinous processes being well developed. Some filaments belonging to the posterior spinal nerves ran across the cavity of the sac to its anterior wall, in the coverings of which were lost. The sac was somewhat

thickened at its neck, and its internal membrane presented evident traces of inflammation.

CASE III.—Spina-bifida in a lad, *æ*t. 17.—In March, 1844, I saw this case with Dr. Page. The tumor, which had increased with the growth of the lad, was then of the size of an adult's head. It occupied the whole of the posterior sacral region, and had a very broad basis; the skin covering it presented its natural appearance, but the tumor was, throughout its whole extent, quite transparent. The boy, who was apparently of a weakly habit, had lately had a very severe attack of influenza, which had left him in a very debilitated state. He had perfect command over his inferior extremities, and, some little time before his illness, he had walked four miles without any fatigue. He complained of a burning sensation running down the back part of both thighs to the soles of the feet whenever the tumor was struck. From his birth he had never been able to retain his water, which constantly dribbled away; and he had but very slight command over the sphincter ani. He had no pain in his head, which was well formed, and of the average size; his intellect appeared to be well developed. Pressure upon the tumor had no effect either on the brain or on the tumor itself.

The parents of the lad, who discovered the tumor shortly after his birth, were advised by a surgeon whom they consulted not to allow the tumor to be meddled with, as the child was in good health, and did not appear to suffer any inconvenience from it. The boy was brought up with the other children, but had not for some time past entered into their games, for fear of the tumor being injured.

CASE IV.—Spina-bifida in a young woman, *æ*t. 25.—In March, 1844, I was asked by Mr. Walshe to see this case with him. The patient was delicate-looking, but appeared to enjoy excellent health. The tumor, of the size of a child's head, had for the last few years remained quite stationary; it occupied the middle part of the posterior sacral region. The sac containing the fluid was very firm and thick; the skin which covered it was thickened and coriaceous, and, at the most prominent part of the tumor, presented an excoriation, of the size of a shilling,

with hard, elevated edges: on another part of the tumor was a large, warty growth, presenting the appearance of the warty growths sometimes met with in cicatrices. The basis of the tumor was broad, and appeared, at one part, to be surrounded by a thick elevated ridge. The inferior extremities were not in the slightest degree affected, and no inconvenience was felt when the tumor was either struck or firmly pressed upon. When sitting, she was not able to retain her water, but she was not thus inconvenienced when walking; the sphincter ani did not appear to be affected; her bowels were generally costive. She was a hard-working woman, and had always enjoyed very good health. The tumor, to which she had now become accustomed, caused her but little inconvenience.

When the tumor was first discovered, it was very small, and entirely disappeared under pressure. She was ordered, by Sir William Blizard, to whom her parents took her, to wear a bandage which slightly compressed the tumor; for some time she continued to wear the bandage, but she had, for some years past, abandoned all treatment, as the tumor no longer increased in size.

REMARKS.—Spina-bifida may, it is well known, be found in any part, either at the anterior or posterior surface, of the vertebro-sacral column; but its common situation is at the posterior part of the lumbo-sacral region.

The existence of this disease is generally explained by an arrest in the development of the osseous tissue, which, M. Cruveilhier thinks, is, in some cases, the consequence of adhesions having taken place between the integuments and the coverings of the spinal chord, before the cartilaginous tissue of the laminæ was formed; by these adhesions the chord is kept out of the canal, and consequently prevents the formation of the laminæ in the corresponding region.

The connexion which generally exists between the chord, or the nerves, and the walls of the sac, is a point of the utmost importance.

Some cases are related, by various authors, in which neither the chord nor the nerves had any connexion with the sac; these parts followed their usual

course down the spinal canal; but, in by far the greater number of cases that have been placed upon record, the nerves presented some kind of connexion with the sac. Of *twenty* preparations of spina-bifida, occupying the lumbo-sacral region, which I have examined in various collections, I have found but *one* in which the nerves were not connected with the sac.

With regard to this connexion of the nerves with the sac, it appears that the two following general rules may be laid down. 1st, if the tumor corresponds to the two or three upper lumbar vertebræ *only*, the chord itself very rarely deviates from its course, and the posterior spinal nerves are generally the only branches which have any connexion with the sac. 2d, if the tumor occupies partly the lumbar, and partly the sacral region, then, *generally, the chord itself*, and its nerves, will be found intimately connected with the sac. M. Cruveilhier believes, from his dissections, that this connexion is *constant*.

Various reasons have been assigned for this connexion of the chord with a tumor lying over the sacrum, and Morgagni enters into a long discussion about this point; but, for his suggestions, I must refer to his work, "*De sed. et caus. Morb., Ep. xii.*" The true explanation is, that, in these cases, the disease takes place during the first months of fetal life, when the chord is situated in the sacral canal.

For a detailed account of the various ways in which both the chord and the nerves have been found connected with the sac, I must refer to Mr. Stafford's Treatise on the Spine.

In by far the greater number of cases the fluid is found in the *sub-arachnoid* cellular tissue, the visceral arachnoid being more or less extensively stripped off from the chord and its nerves; in a few cases only, the fluid is effused into the *cavity of the arachnoid*. This difference in the situation of the fluid will, I think, serve to explain some of the varieties which have been observed as to the connexions of the chord, or the nerves, with the sac*.

1. If the fluid is effused into the cavity of the arachnoid *previous to the formation of any adhesions between the two*

* It must be borne in mind, that the disease, in a large proportion of cases, takes place at a very early period of fetal life.

layers of that membrane, no nerves will, I think, be connected with the sac; for the fluid, thus effused, accumulating at that point where it meets with the least resistance, will project at the back part of the spine, which is deficient, and pushing against the bodies of the vertebrae, the chord, and its nerves, it will serve to keep them in their proper situation.

2. In those cases where the chord and its nerves have been found passing through the cavity of the tumor, the fluid has, I think, been effused into the *sub-arachnoid* cellular tissue after *partial adhesions* had formed between the chord, with its nerves, and the two layers of the arachnoid at the posterior part; the membranes having been subsequently made, by the accumulation of the fluid, to project where the least resistance was offered, have carried backwards the adherent chord and its nerves, the anterior branches of which, having to pass to their foramina, have thus been made to intersect the cavity of the tumor.

3. If the chord and its nerves are found spread out upon the posterior wall of the sac, without passing through its cavity, the fluid has been effused into the *sub-arachnoid* cellular tissue after *extensive adhesions* had firmly united the chord, or its nerves, and the two layers of the arachnoid at the posterior surface; these parts, thus united, having been subsequently forced outwards by the accumulation of the fluid which, in these instances, necessarily takes place before the cord, the anterior spinal nerves will be found running along the walls of the sac to reach their proper foramina.

If the *anterior* spinal nerves are connected with the tumor, we shall find branches going to the sac, and returning from it to reach their respective foramina, through which they always pass, to form the different plexuses; but if some of the *posterior* spinal nerves only are out of their place, they will *generally* be lost in the walls of the sac, or in the neighbourhood to which they are distributed.

The greater or lesser degree of paralysis of the inferior extremities which sometimes accompanies spina-bifida, may be generally explained by the connection of the sac with the chord and its nerves, which have, in some cases, been found soft and pulpy, and in other cases

wasted, or altered in structure, by the pressure to which they have been submitted.

Several cases of persons affected with spina-bifida living beyond the adult age have been placed upon record. The walls of the sac, in these cases, generally become thickened and firm, and the tumor then remains stationary, as in Case IV. in this paper; but in Case III. it will be seen that the tumor, of the size of an adult's head, has gone on increasing up to a very recent period, and that its walls, instead of being opaque and firm, were thin and transparent, so that the lad was in constant danger of having serious mischief produced, even by a slight accident. In some of these cases it has been remarked that there was more or less paralysis, either of the sphincter vesicae or of the sphincter ani, and sometimes of both, even when the inferior extremities were well developed, and not in the least degree affected with paralysis. Such was the case in the patients whom I have mentioned (Cases III. and IV.)

Treatment.—The remarks which I have to make upon this point will be confined to the radical cure of this disease.

The dissections of the cases of spina-bifida which have been published, and the preparations which are to be found in our museums, at once point out the rashness of attempting to remove these tumors either by ligature or by the knife. I do not consider this remark to be in the least invalidated by the success which is said to have attended the practice of Mr. Dubourg, who has published in the *Gazette Médicale de Paris*, 1841, a paper upon the radical cure of spina-bifida. Mr. Dubourg operated upon three cases: in one, a ligature was applied to the tumor—the patient died two days after the operation; in the other two, which terminated successfully, the sac was removed by the knife, and the lips of the wound were brought together by hare-lip pins and sutures. The successful termination of these two cases was, it must be confessed, very fortunate; but this success ought not, in my opinion, to lead any surgeon to adopt so rash a practice; for, laying aside the question of thus opening the theca vertebralis, there still remains the fact that, in the majority of cases, some nerves are connected with the sac, and that, when

the sac corresponds to the sacrum, the chord itself is *generally* connected with the tumor. In one of M. Dubourg's cases the tumor was in the loins; in the other it was at the lower part of the cervical region. The sacs were examined after the operation, *but no nerves were connected with them.*

Several cases, in which the plan of treatment adopted by Sir A. Cooper has completely succeeded, have been placed upon record by various authors; but in these cases two points of importance have not, I think, been sufficiently considered, and I would therefore lay down the two following general rules:—

1st. The tumor ought never to be punctured along the mesial line, especially in the sacral region; for it is generally at this part that the chord and its nerves are connected with the sac. The puncture is to be made at one side of the sac, and at its lowest part, so as to diminish the risk of wounding any of the nervous branches.

2d. The instrument ought to be a grooved needle, or a small trocar; for if a lancet is used there will be a greater risk of wounding some important part contained in the cavity of the tumor.

REPORT ON THE ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from p. 440.]

DURING the year 1841, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2167 women—Of which cases,

27 were twins—about 1 in every 80½ cases: of these in 18 both heads presented; in 7 the presentations were head and breech, or some part of the inferior extremities; in 1 both breech or inferior extremities; and in 1 the head of the first child, and the head, hand, and feet of the second. The children, in 13 cases, were both boys; in 10 both girls; and in 4 of different sexes. In one case the placenta of the first child passed three

hours before the second was born; there was no flooding, and the second child was born living.

1124 were males.

1070 were females.

2143 were presentations of some part of the head, of which 7 were face presentations—about 1 in every 313½ births.

44 were presentations of the breech, or some part of the lower extremities—about 1 in every 51½ births; of these 10 were twins.

7 were transverse presentations—about 1 in every 313½ births. All these children were born still. One, a premature twin, passed doubled; another I delivered by decapitation, after having eviscerated it, ten hours after the membranes broke, being unable to turn. In another case, when I was sent for I found the arm had been amputated by the surgeon previously in attendance after ineffectual attempts had been made to turn. The uterus was ruptured, and I had no difficulty in bringing down the feet. This was the woman's sixth child; they had all been preternatural presentations; one before a shoulder; the other four breech. She had a slightly distorted pelvis.

In 1 case the placenta was wholly implanted over the os uteri. The woman was delivered by "turning," and did well. The child was born living.

10 were complicated with alarming hæmorrhage before the birth of the child, *not* the result of placental presentation—about 1 in every 216½ cases. Two of the children presented with the breech; 4 were born living, 6 still; one of which was a breech case. In 7 of these cases the hæmorrhage was controlled by the rupture of the membranes. In 3 the women were delivered by "turning;" one of whom died shortly after. One died also an hour after the natural expulsion of the child; there was no hæmorrhage after the membranes were broken, but she had lost so much blood before that, that although the uterus retained sufficient power to expel the child, she never rallied: the others all did well. In one case the hæmorrhage, which was to an excessive degree, was occasioned by a violent blow on the abdomen. Letting off the liquor amnii did not cause a diminution of the flooding; the child was turned, and born with

animation suspended, but was restored, and the woman did well. The whole of the placenta was separated from its attachment to the uterus before the operation was commenced, as, on the introduction of the hand, I found it lying quite loose in the cavity.

In 16 cases the placenta was retained within the uterus, either by atony, or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces—about 1 in every 135½ cases. With all there was considerable hæmorrhage. Two were twin cases. All the women did well.

5 were delivered by craniotomy, under head presentations—about 1 in every 433½ cases; all these women did well. Besides these, the head was opened in one, under a breech case. The uterus had prolapsed during pregnancy; and in labour the os uteri, which was very rigid, protruded considerably beyond the external parts during the passage of the child. When the head was pressing against it, as it still gave great resistance, and the arteries in the cord had ceased to pulsate, I perforated the head, and evacuated the brain, to preserve it as much as possible from injury. This woman recovered from the effects of her labour; but in the second week she employed herself about her domestic affairs as usual; she also indulged in porter and spirits, was attacked with hysteritis, and died in the third week. She was the subject of prolapsus uteri when not pregnant.

In 1 case premature labour was induced between seven and eight months, in consequence of a deformity of the pelvis. The woman took the ergot at intervals of four hours for two days, under the action of which medicine the os uteri became soft and somewhat opened; I then perforated the membranes, and in a few hours the child was born living.

In 1 case the uterus was ruptured as above stated. On examination after death the laceration was found to be at the back part of the body, extending in an oblique direction upward towards the right broad ligament; the woman died on the fourth day.

6 women died either within the puerperal month, or from puerperal causes—about 1 in every 361 cases; only 5 however, as a consequence of labour,

for one died of apoplexy, not attributable to a puerperal cause—about 1 in every 433½ cases.

2107 children were born living.

87 children were born still—about one in every 25½ births.

Of the Deaths,

2 were from hæmorrhage, both within an hour after delivery; in both the flooding occurred before the birth.

1 from ruptured uterus, under a shoulder presentation, on the fourth day after delivery.

1 ten days after labour, from peritonitis.

1 in the third week, from hysteritis, the consequence of great imprudence, after having suffered a severe and dangerous labour.

1 a week after delivery, from apoplexy.

Of the still-born children,

14 were premature.

18 were putrid, at full time, or nearly so.

9 were breech presentations, at full time, or nearly so; in one case the head was opened.

7 were transverse presentations, at full time, or nearly so.

6 were under accidental hæmorrhage.

2 were under lingering labour.

5 were delivered by craniotomy, head presenting.

1 after the uterus had burst.

With 6 the funis prolapsed by the side of the head. The funis descended also in two other cases; in one the child was born strong and hearty; in the other with animation suspended, but it was restored.

With 1 there was a tight knot upon the funis.

4 were monstrous; two of these acephalous.

1 woman had suffered a severe accident.

1 woman was ill with influenza.

1 child was smothered in the membranes, being born before the midwife arrived.

11 were at full time, not putrid, nor delivered by art; there being no assignable cause for their not being born living. Of these 4 were twins.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Enchiridion Medicum: or a Manual of the Practice of Medicine, the result of fifty years' experience. By C. W. HUFELAND. Translated from the 6th German Edition, by Casp. Bruchhausen, revised by K. Nelson. New York, and London, Baillière.

THE ordinances affecting the vestal virgins of old have been often quoted. They were received into the Temple not before six, nor later than ten years of age. During ten years they were engaged in learning their duties; during ten years they practised them; and during ten years they taught them. After this they were at liberty to join the world again, to marry or to live free as they pleased. It were an excellent provision in the anticipated "Medical Provision Bill," were there a clause to the effect that no physician, surgeon, or apothecary, should be suffered to write on any subject of practical medicine or surgery until after he had been engaged during ten years in learning his profession—say from twenty to thirty; and during ten or more years in practising it—say from thirty to forty or fifty; after this it would be competent for him to write,—to take on himself the business of instructor. What a world of labour we should then be spared! How pleasant would the critical tasks prove which we should then have in hand! The only difficulty would be, that we should be without the supply of books necessary to afford us subjects for our hebdomadal analysis or criticism; but the excellence of the article would undoubtedly make up for its rarity, and so there would be no actual loss.

One of the best (? the best) books we have on the practice of medicine is "Heberden's Commentaries;" and this was not published till after the author's demise at the age of ninety years and upwards. It is a small volume, as all the world knows, but of inestimable price. Hufeland had probably Heberden in his eye, when he wrote his "Enchiridion," though we do not recollect that he imitated that distinguished physician in not suffering his work to appear till

after his death; it ran, if we recollect rightly, through two or three editions during his life-time, the proceeds of the sale going to aid the funds of a society for the relief of decayed medical men.

Hufeland was probably one of the purest embodiments of what we call the "practical man" in England; he did not neglect science, indeed; he was kept to its level by means of the Journal and Bibliotheca which he edited for so many years; but it was therapeutics which seemed to engage his attention, to have all his devotion. The consequence of this could have been foretold: Hufeland had immense practice—the unbounded confidence of the public. He had what may be called a "believing mind,"—one of the happiest of endowments for the practitioner of medicine: he had not only a holy faith in rhubarb and senna himself, but he inspired the same faith in those he visited; and, judicious in his prescriptions, his medicines wrought with a double power—they influenced the patient morally as well as physically, and in the most advantageous manner.

But then the comparative absence of "philosophy" seems to have made his life much less influential than it otherwise would have been: he is said to have left no school; no host of distinguished pupils, each an enshrinement of the master's spirit in a more advanced and perfect state. Be this as it may, Hufeland lived usefully to himself, to his patients, and, through the medium of his Journal, to the profession, for a long series of years; and in the "Enchiridion," whose title stands above, we have the condensed results of the experience of his entire life. The author's motto shews much of the man; it is brief, and to this purpose:—

What life hath taught me; what I have approved
Of use through life, in truth and thankfulness
I here present at fair Hygeia's shrine;
In death I still would be your friend and helper.

Hufeland was, in fact, like so many other distinguished members of our profession, one of the best and most charitable of men; he was not only an ornament to his order, but to humanity.

Any attempt to analyse such a work as the *Enchiridion Medicum* were vain; we can only recommend it to the notice of our friends. They will find hints there that may prove useful to them in more ways than one; in the treatment

of obstinate chronic diseases especially. In the original it has been long familiar to us, and frequently turned to with interest. The American translation appears, if not elegant, yet faithful; and that suffices in such a book. It is not in every medical work we purchase that we can have the results of fifty years of experience.

MEDICAL GAZETTE.

Friday, July 5, 1844.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

THE HARVEIAN ORATION, BY DR. OGLE.

WHEN the *Times* newspaper gives a full report of aught in the shape of medical news, we feel as matter of course that we have been fairly anticipated, and that any farther word *we* have to say must be "stale, flat, and unprofitable" to our readers' eyes or ears. Nevertheless, the Harveian Oration is one of those incidents in the course of the year, that bids us pause and pay our tribute to the memory of intellectual greatness.

The main drift of Dr. Ogle's discourse was to insist on the necessity of a most liberal preliminary classical education for the young men destined to the medical profession. In this country, up to the present time, classical acquirement is indeed almost the sole evidence we have that a man has been liberally educated. There is little else but classics attended to in our oldest and best public schools. At the time these seminaries were founded, Latin was the only language in which the man who had a taste for letters could find any food to meet it; the dark and the middle ages were mental blanks; and with the revival of letters, there was nothing for it but to overleap these benighted periods, and to fall back upon the writings of Cicero, and Tacitus,

and Livy, of Horace and of Virgil; and by and by even to ascend the stream of time, and to comprehend Demosthenes and Herodotus, Homer and Æschylus, &c. This was the natural, and under the circumstances the necessary course; and the influence which it has had extends to the present hour. Whether it might not now be advantageously departed from is no longer a question in our mind. We think that it might; seeing that we have created a literature for ourselves more copious, and no whit less noble, than that of either Greece or Rome, and enriched ourselves besides with the acquisition of sciences which were unimagined in former ages. We have noble poetry, both epic and lyric, stirring oratory, tragedy and comedy, such as it never entered into the mind of man to conceive before; history as vigorous and as interesting as was ever written, and moralists, and essayists, and romancers, who have made us heirs to works each and all of which are as well calculated to develop the understanding and the feelings, as aught that Greece or Rome has left us. The old system *need not* any longer be followed; we are amply independent of it:—but whilst it is followed, let us insist on its being pursued to purpose; let us have our physicians and surgeons men deeply imbued with the *literæ humaniores*; we would have none suffered at this present time, and whilst our educational system continues as it is, to enter upon the study of the medical sciences, properly so called, who had not given preliminary proof of having made satisfactory progress in classical polite learning, as well as having mastered the elements of the physical sciences.

We trust, for our part, never to see the divorce effected between our noble profession and the English Universities, to which Dr. Ogle alludes as

threatened. We should even like to see it *imperative* on the future physician and surgeon to have passed some years at Oxford or at Cambridge; not occupied, indeed, as the young men of the present day, so commonly possessed of independent fortune, who crowd their noble halls, are occupied, with boat-racing, and horse-racing, &c. but as we love to imagine Milton or Locke to have been occupied—seriously, soberly, profitably, not only to themselves but to mankind—drinking at the fountain-head of lore, improving their opportunities, fashioning their own noble minds to surpass the noble minds that have gone before them, and bent on making the world heirs to their immortality; for there is no nobility admitted now that is not of the mind, and there is no immortality among men that has not its roots in worthy thoughts and deeds. Let Oxford and Cambridge perfect their system of education for medical men, and they can defy any legislature to take away their privilege of granting degrees—the only degrees worth having in the present day—certificates of superior education; and the effects of this—men visibly beyond their fellows in conduct and acquirement. No; *sit perpetuus Nuptus!* say we. Our profession would, indeed, suffer severely from the threatened divorce between our Universities and medicine; but we believe that society would suffer still more, and is still more interested than we in maintaining the union that still exists between them.

And now we are going to be guilty of what we fear will be held a monstrous heresy with those among our readers whom we esteem most.—We wish this Harveian Oration were delivered in English. Making no pretensions to extensive classical lore ourselves—we had not the advantage of being bred at Eton or Harrow, and

finished off at Oxford—we are still a competent Latin and Greek scholar; but we will own that we are slow to follow words in any language to which our hearing is not tutored. This may be from some defect of ear on our part; though it is a defect that we know to be common enough: every well educated man and woman in the present day, for instance, reads, and even manages to speak indifferently, the French language; but of all the English folks who frequent the French play, how many succeed in following the dialogue with perfect understanding of its meaning, aided though it be by pantomime the most expressive? We believe not a dozen of the whole assembly, and these all of them persons who have had their hearing cultivated—habituated to the sounds of the spoken French tongue. We do not scruple to say, that even Dejazet and Jenny Vertpré are tiresome to us, now that we only go to the French play once in a season—we have not been there at all this year—and why? Because we cannot follow the speakers without the book; because our ear, that has in former times drunk in with delight and understanding the voices of Talma, of Dache-nois, and of Mars, has become unaccustomed to the sounds, and we sit abstracted from the scene, unengaged with what is passing, chewing the cud of sweet and bitter fancy, the morsel something very different from the matter in hand. It is even so with the Harveian Oration: delivered in Latin, it necessarily falls, in a great measure, meaningless on the ear; and though it would look ignorant and uncultivated to own so much, we can nevertheless perceive by the blank looks of our brethren at large, that the truth is, very few of them follow the orator with perfect understanding through the whole of his discourse. Some few—very few—do follow; and they smile,

or they murmur, or break out into louder applause from time to time; and then the others smile, or murmur, or applaud, in imitation. Massillon and Bossuet would never have had their congregations starting to their feet with one consent, had they been delivering themselves in Latin. Fettered themselves, speaking in a foreign language, their words could never have had power to move in the highest degree, even though they had spoken to perfectly intelligent ears; addressing organs that were either wholly sealed against their meaning, or only partially opened to its import, how could they have hoped to commove at all? Demosthenes, addressing Greeks, thundered his orations forth in Greek, and bore all before him on the tide of his burning words. How would he have succeeded had he addressed his countrymen in Sanscrit or Chaldee? Germany, struggling into intellectual and literary existence, so lately as the time of the Second Frederic of Prussia used the jarring French, as she had hitherto employed the more grandiloquent Latin, as the medium of making herself heard. But this period soon passed; and with her Lessings and her Klopstocks, her Herders, Schillers, and Goethes, she threw off her foreign chains, and in the course of little more than half a century has taken her place in the republic of letters and science, second only to England; and second solely because England had her Shakspeare and her Milton, her Newton and her Bacon, to boast of.

The Harveian Oration ought to be in English. The mass of orators would probably be tame enough then; they could not be less effective than they have generally yet been, delivered in Latin. Now and then some one would be found with soul and oratory enough to rise to the full height of the noble argument; and single orations would

then be produced that would outweigh the contributions of centuries in Latin diction. We heartily wish Dr. Ogle would give us his excellent oration in English. It were one of the legitimate things connected with our profession which the public might read, and which could not fail favourably to impress even the fair sex with the humanity, the taste, the high honour, the learning, and the ability, of the men engaged in the legitimate practice of medicine. An opportunity of this kind, in these days when we are so commonly judged of by successful jugglery and mere mockeries of science, ought not to be neglected.

BILL FOR REGULATING THE MEDICAL PROFESSION.

IN the House of Commons on Monday night last, Mr. Macaulay begged to remind the Right Hon. Baronet, the Home Secretary, that on more than one occasion during the session he had expressed his intention of bringing in a bill for regulating the medical profession, not with the view of passing it this session, but that it might be printed, in order to let the profession have an opportunity of considering its provisions during the recess. He would be glad to know whether it was the intention of the Right Hon. Baronet to lay such a bill on the table before the close of the session?

Sir J. Graham said the House would recollect that he had on more than one occasion expressed his intention of bringing in such a bill. He did not, however, wish to bring it in without having the opportunity of stating the grounds of it, and its provisions in detail. He should, however, ask leave to lay such a bill on the table before the close of this session.

This is somewhat indefinite. The Right Hon. Baronet, the Home Secretary, does not wish to bring in his bill

without the opportunity of stating the grounds of it, and its provisions in detail; but he will ask leave to lay such a bill on the table before the session closes. If the Home Secretary do not see the opportunity he craves, he is therefore not bound to let us see his bill this session. Did he understand that his bill was really now become a thing *necessary* to the medical profession, we trust Sir James would be induced to yield to its strong desire to be informed of his purposes. When we look at the mass of business still to be got through in the House of Commons, in contrast with the period of the session, and the known and continually increasing eagerness of the honourable members to get out of town as the month of August approaches, we do candidly confess that we despair of seeing the opportunity present itself for going into "the grounds and provisions of the bill in detail."

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, June 18th, 1844.

THE PRESIDENT IN THE CHAIR.

Case of Acute Retinitis, caused by the use of the Microscope. By WILLIAM WHITE COOPER, Surgeon to the North London Ophthalmic Institution, &c.

THE following case is considered interesting by the author, as offering a warning to those microscopical investigators who are in the habit of pursuing their researches with powerful instruments and the aid of strong and concentrated light.

Mr. G—, a gentleman well known for his remarkable skill in minute and microscopical dissection, was engaged, on Friday, the 29th of April last, in dissecting the nerves of the human tongue under a powerful microscope, and in a situation exposed to the full influence of the sun, which, although occasionally obscured, burst forth at times with great power.

The nerves, having been cleanly dissected, were of a dazzling white, and whilst he was intently regarding them through the microscope, the sun, which had previously been obscured, suddenly shone forth with all its brilliancy upon them.

Acute pain was instantly felt in the eye, pervading the whole globe, so severe as to cause Mr. G— to start back and utter an exclamation. He paused from work, but for some time was not able to see anything with that eye, the spectrum of the sun continuing before it, whether closed or open. In about twenty minutes, however, this, as well as the pain, had sufficiently subsided to enable him to resume work with the other eye, but the injured organ was not free from uneasiness until the evening.

The following day the eye was not painful, and he incautiously used it to complete his dissection, when the very same occurrence took place as on the previous day, the reflected rays of the sun being thrown powerfully upon the retina. This time the shock was excessive: great and deeply-seated pain pervading the whole globe, with much intolerance of light, immediately set in, and the spectrum of the sun was most distressing. He remained in acute suffering all the evening and following night, and on the next day (Sunday) it continued to increase with a sensation of fulness and tenderness of the globe, and extreme intolerance of light. Fomentations failed to afford relief, and when he consulted Mr. Cooper on Monday morning, the following were the symptoms:—acute, deep-seated pain in the eye, exquisite tenderness especially at the upper half of the globe, great intolerance of light, profuse lachrymation, any attempt at vision produced luminous spectra, pupil concentrated, iris natural, conjunctiva but slightly injected, pulse feeble and irritable: he complained of weakness and mental depression.

He was sent to bed in a darkened room, and ordered to apply twelve leeches around the eye, to foment, and to take a purgative pill and dose. Mercury, he stated, always disagreed with him; and this, which is so important an auxiliary in such cases, was therefore obliged to be used with great caution.

The next day he was rather easier; friction of the brow and temple with mercurial ointment and opium was directed, Pil. Hydrarg. with Conium ordered at night, with saline and antimony at intervals. The following day all the symptoms were alleviated. The antimony was omitted, but the mercurial directed to be continued.

On Thursday a still greater improvement was manifest, the eye being perfectly free from pain except when exposed to light.

There was, however, great debility and general exhaustion, and half a grain of Quinine, twice a day, with a moderate meat diet, was ordered. The mercurial friction being continued.

This treatment, with counter-irritation behind the ear, and the use of a mild astringent collyrium, was steadily pursued

for a week with advantage, although the least exertion of the eye immediately produced luminous spectra.

The further treatment of the case presented nothing remarkable. The eye gradually and steadily recovered, and is now perfectly well.

From the state of general debility in which the system was at the time of the attack, taken in connection with the constitutional antipathy to mercury, the free exhibition of that medicine was inadmissible, whereas the patient did perfectly well under its cautious use, the system being at the same time supported by a nutritious diet, and the careful exhibition of tonics.

A few Remarks upon the Origin and Treatment of Syphilis, and upon the extraordinary prevalence of the disease in the East as compared with the West Indies, with the marked influence of famine in extending its ravages. By JOHN CLARK, M.D. Staff-Surgeon (2d Class). [Communicated by Dr. GORDON, Deputy Inspector-General, Vice-President of the Society.]

THE author presents a table showing the number of patients admitted into hospital for gonorrhoea and syphilis in regiments stationed in the East and the West Indies during the year 1829, and he deduces from it that more cases of these diseases occurred in each individual regiment in the East Indies, than were met with in the same time in five regiments which served in the island of Jamaica. In another table, which contains the admissions for the same diseases in the 13th Regiment of Dragoons, during fifteen years that it served in the East Indies, the author makes a contrast between the years of plenty and those of famine; and he shows that there was an extraordinary increase in the number of cases during the latter compared with the former years. To account for these differences, the author enumerates various circumstances in the mode of life of the native females in the two parts of the globe, which may explain the greater freedom from the above diseases in the West Indies compared with the East; and he adverts particularly to the encouragement given to marriage, as well as the exception from famine among the Negroes in the West Indies, as contrasted with what is met with in the East.

The author concludes by discussing at length several general questions relating to syphilis and its treatment.

An Account of the Dissection of a Cyst containing Seminal Fluid. By JAMES PAGE.

THE cyst described in this paper was situated on the upper and inner part of the epididymis, external to the tunica vaginalis. It was about $\frac{1}{4}$ of an inch in diameter; its walls were thin but opaque, and composed of a fine fibro-cellular tissue, lined by a very delicate tessellated epithelium. It was filled with a milky-white, non-albuminous fluid, in which there were numerous dead spermatozoa and spermatic granules. The most careful examination showed that the cyst had no open connection with the vas deferens or any part of the seminal tubes; it was on every side closed and isolated from the surrounding parts.

In explanation of this and similar cases of cysts containing seminal fluid (for their contents are not merely spermatozoa floating in an ordinary fluid, but semen more or less perfectly formed), the author suggests that their occurrence is analogous to that of cysts, most commonly found in the ovaries, containing hair, epidermis, sebaceous matter, and other products of the skin. In these cysts either the whole or part of the wall is formed of true skin-tissue, with its various imbedded organs of hair-follicles, sweat-glands, &c., all of new formation; a fact, which is more remarkable than that, close by the organ by which the materials of the semen are naturally produced, and therefore in some measure under its influence, cysts should be formed which can secrete the materials of the seminal fluid. And as, in the cysts containing hair, &c. these organised secretions are often found imperfectly formed, so in these seminal cysts the semen is probably sometimes very imperfectly organised; in evidence of which, the author gives an account of the dissection of two cysts like the first described, in which bodies like imperfectly formed spermatozoa and spermatic granules were found in a thin milky fluid.

In the first described case there was a cyst containing about four ounces of fluid like that of ordinary hydrocele of the tunica vaginalis, but no organic particles. This cyst was in front of the spermatic cord, and completely separated from the cavity of the tunica vaginalis; but it had been tapped in the belief of its being a common hydrocele, and its true nature was not discerned till it was diseased. The author suggests that in the cases in which it has been supposed that the fluid of common hydrocele contained spermatozoa, the fluid has been drawn from cysts like this, and not from the tunica vaginalis; and that, as the cysts in which hair, &c. has been formed, after a time wholly degenerate and lose their cutaneous tissues, so seminal cysts may, after secreting seminal fluid for a time, degenerate and secrete a common serous fluid; or serous fluid from one part of their walls and seminal fluid from another.

Proposals for the improvement of Diagnosis in the investigation of the Diseases of the Uterus: with an account of a newly-invented Speculum Uteri. By PROTHEROE SMITH, Assistant Teacher of Midwifery at St. Bartholomew's Hospital; Surgeon to the Hospital for the Diseases of Women; Consulting Accoucheur to the Central London Lying-in Institution, &c.

THE speculum described in the paper consists of a glass cylinder fitted to an outer one of metal, within which it slides. The metallic tube has its inner surface highly polished, the reflecting powers of which are still further increased by the glass cylinder which it contains. The edge of the smaller or uterine extremity is rounded into a smooth ring, which projects slightly from the inner surface, facilitating its introduction per vaginam, and also presenting a limit to the farther progress of the internal tube. In its side is cut an oval aperture of about three inches in length, and two in breadth, and extending to within an inch of the uterine end of the cylinder. The other extremity terminates in a rim, having its surface blackened for the purpose of absorbing any rays of light which might otherwise be reflected so as to dazzle the eye of the observer. There is also a corresponding rim to the glass tube, by which it is more easily withdrawn from the metallic cylinder.

The author had found this instrument of great use in examining the condition of the vagina. With this view the speculum should be passed per vaginam to its full extent, when, by partially withdrawing the glass tube, a portion of the lining membrane would be seen protruding through the oral aperture into the cavity of the cylinder, and, by turning it gently round, every part of the canal would be successively brought into view. Thus it had been found to be of much assistance in cases of vesico-vaginal fistula, when the opening was so minute as to perplex the operator, if not to elude his search.

For the application of leeches to the cervix uteri or the surface of the vagina the instrument is also well adapted. To accomplish this, two fine wire-gauze tubes are supplied; one for the os uteri, the other for the vagina. In the former, one end only is open, through which the leeches, previously placed within it, are brought into immediate contact with the os uteri by means of a wire-gauze piston. In the latter, each end is closed, and there is an oval aperture similar to that in the metallic tube. The aperture in the outer tube being directed to the part of the vagina about to be leeches, the wire-gauze cylinder containing the leeches is introduced, and turned round until the two openings correspond.

After enumerating several of the uses to which the instrument may be applied, the author directs particular attention to the superior advantage which it possesses over other instruments of the same kind, that it enables the practitioner to feel with his finger, as well as to see, the diseased parts, in the course of his examination.

Case of Fistulous Communication between the Intestinum Ileum and Urinary Bladder, simulating Stone in the Bladder. By W. C. WORTHINGTON, Esq. Surgeon to Lowtoft Infirmary, and Fellow of the Royal Medical and Chirurgical Society. [Communicated by JAMES COPLAND, M.D. F.R.S. &c.]

THE patient, a female, 65 years of age, previously enjoying good health, began four years ago to suffer from pain in the right iliac region, the cause of which could not be satisfactorily traced. Having continued to experience this pain, symptoms indicating disturbance of the urinary organs commenced in November 1842. Her pain was now much aggravated: she had frequent and painful micturition, the urine was very ropy, and highly offensive, and fragments of extraneous matter, the exact nature of which was not ascertained, were often found deposited from it. On sounding the bladder, no calculus was felt, but there was a grating produced by moving the instrument, which led to its being supposed that some malignant ulceration had taken place in the coats of the bladder. The treatment consisted chiefly in giving anodynes to relieve the pain. The patient survived about four months, and died from an attack of diarrhoea.

On examining the body after death, adhesions were observed between the convolutions of the intestines and the pelvic viscera. By further dissection, it was found that a fold of the intestinum ileum was closely adherent to the fundus of the bladder, and that a communication existed between the two cavities, by an ulcerated hole which extended through the coats of the intestine and the bladder, and was sufficiently large to admit the point of the index finger. On slitting open the bladder, it was filled with feculent matter and undigested food, such as currants, seeds, and other vegetable matter. The coats of the ileum, near where the ulceration had taken place, were thickened and indurated, and the canal consequently stricured.

The author concludes by quoting Dr. Copland's Dictionary of Practical Medicine, where similar cases are referred to, with interesting observations on fistulous communications between the intestines and other viscera.

Cases of Mollities Ossium: with Observations. By S. SOLLY, Esq. F.R.S. Assistant Surgeon to St. Thomas's Hospital; Surgeon to the General Dispensary, Aldersgate Street.

THE author of this paper relates two cases of mollities ossium in the adult, which have lately come before him.

The first case was that of a young woman, aged 29, in whom the disease first exhibited itself seven years previous to her death, by a fracture of the clavicle caused merely by the exertion of lifting a stool. The disease advanced in the spinal column and skull, in which latter portion of the skeleton it was of such an active character that the membranes and substance of the brain became secondarily affected, and insanity was the consequence. When in St. Luke's Hospital, in 1840, whither she was removed in consequence of her mental derangement, the lower extremities gave way, and depriving her of the power of walking, she was obliged to push herself about the floor upon her haunches. On the 11th of April, 1842, she was admitted into Hanwell, where she died in the October following, the disease having attacked almost every bone in the body.

The second case was that of a woman, aged 39, who: Mr. Solly admitted into St. Thomas's Hospital a few days before her death. In this case the progress of the disease was rather different: it commenced in the lower extremities, and attacked the rest of the skeleton subsequently. The immediate cause of death was suffocation from contracted thorax, one lung being wholly impervious to the air, and the other nearly so.

Mr. Solly proposes that this disease should be distinguished from other kinds of softening of the bones, by the title of *Osteomalacia rubra et fragilis*, from the colour which the bones invariably exhibit in their interior when divided, and the fact that they almost invariably break, and not bend, as in rickets. The two adjectives appear advisable, as the redness in the interior exists in the early stages of rickets, an essentially different disease, while their liability to fracture is not characteristic of this complaint alone. From a comparison of the symptoms during life with the appearances after death, he has been led to believe that the disease is of an inflammatory character; that it commences with a morbid action of the blood-vessels, which give rise to the severe pain in the limbs invariably attendant on it, but more especially on its commencement, and exhibits itself after death by an arterial redness of the part. The absorbent vessels are at the same time unnaturally excited, and the earthy matter of the bone is absorbed and thrown out by the kidneys in the urine, which excretion is sometimes so abundant, that, as in the last

case, it clogs up the calices and pelvis of the kidney, and forms a solid calculus. The important fact of the excretion of phosphate of lime had not, according to the author, been previously established.

Earthy deposits in the urine have been almost always observed in these cases, but chemical characters have never before been minutely examined or stated. The place of the phosphate of lime in the bones is supplied, he supposes, by that morbid secretion of red grumous matter which has been so universally found in this disease, and which was abundant in both the cases just related. The microscopic examination of this matter, showing cell development in its various stages, confirms the impression that it is an adventitious morbid product, and not simply the fatty matter of the bone altered by effusion of blood into it. He thinks that the enormous hypertrophy of the bones of the skull in the first case demonstrates that mollities ossium is an active disease, and not a mere atrophy; and the inordinate vascularity of the bones of the skull, though unaccompanied by increase of thickness, in the second case, proves, in his opinion, nearly as much. He concludes with several observations on the symptoms and the treatment of the disease. The paper was accompanied with numerous drawings, which represented the remarkable deformities produced by the disease in the two patients, and illustrated the changed condition of the interior of the bones, as exhibited in several sections.

Some Statistical Records of the Progress of the Asiatic Cholera over the Globe. By S. W. J. MERRIMAN, M.D.

THE author's attention was first directed to this subject by being appointed to deliver the Thurston Oration last year at Caius College, Cambridge, taking "*cholera*" as the immediate subject of his thesis. He then found that much authentic information was wanting to render the history of this pestilence complete, and he endeavoured to procure the necessary data for filling up the vacancies.

By the kindness of Sir Wm. Pym, he obtained from the Privy Council Office a copy of the summary of the reports sent up daily to the Central Board of Health, and containing a vast body of most valuable information never published. This summary includes all the cases reported between October 26, 1831, and December 31, 1832; being about 82,000 in number, occurring in 422 places in Great Britain, which he has analysed thus: places in England 277; Scotland 127; Wales 17, and Isle of Man. He has made several analyses of the information thus obtained, and has extracted the returns from the principal places, thus presenting at one view a general idea of the extent of the

ravages of the disease, and also the dates of the first and last cases, the consequence and duration of the disease in each place, the number of cases, deaths, and recoveries, with the proportion of the mortality, and also of the population affected, &c.

This he has prefaced by a very concise account of the progress of the disease over the globe, and has followed it up by a recital of all the facts that have come to his knowledge, of the subsequent history of the disease spreading over America, and the southern parts of Europe, a part of the history hitherto very scanty and meagre.

The author has also copied an account, given by Mr. Henry, Surgeon to the Forces, of the precautionary measures taken at Kingston, in Canada, to prevent the occurrence of the disease in the army by infection, or, if present, to restrain it as much as possible. The barracks were isolated, the soldiers were relieved as much as possible from hard work, but carefully kept at light and agreeable occupations; they were carefully inspected each day; it was noticed with what appetite they took their meals; and any the least appearance of disease arising was instantly attacked by appropriate treatment, so that remarkably few cases, and of course fewer deaths, occurred in the army stationed at Kingston. Saline transfusion was tried with great temporary success, yet although one man was kept alive for seven days by constant pumping, not a single case eventually recovered. Mr. Henry's "favourite remedy was castor-oil, combined with a small quantity of laudanum, given in some grateful and demulcent fluid, as hot as possible; making the patient lie on his right side, for the assistance of gravitation towards the pylorus, and to prevent nausea." This plan he used, he says, in some hundreds of cases. Acetate of lead was found to be very beneficial in the attack of cholera in 1834; also bleeding, where the spasms were strong; but in another form of the disease debility was the characteristic, and in these cases venesection was injurious.

Observations on the recorded Cases of Operations for the Extraction of Ovarian Cysts. By BENJAMIN PHILLIPS, F.R.S. Assistant-Surgeon to the Westminster Hospital.

THE object of the paper is to bring together the results of these operations, for the purpose of determining whether the plan of treatment is to be regarded as a benefit conferred on humanity or not.

Extirpation of ovarian cysts has been practiced, as appears from the tabular arrangement of the cases, at least sixty-nine times. In fifty cases the tumor was extracted; in fourteen cases adhesions or

other circumstances prevented its removal; in five instances no tumor was found.

Of the cases in which the operation was completed, the tumor being extracted, thirty terminated favourably, the patients recovered; in twenty instances the termination was unfavourable, the patients died.

Of the five cases in which no tumor was discovered all recovered. Of the fourteen cases in which adhesions or other circumstances prevented the extraction of the tumors, eight recovered, six died.

The proper way, therefore, according to the author, of looking at this plan of treatment is, to observe the number of cases submitted to operation, and the number of recoveries after the removal of the tumor. He conceives this to be the fair way, because what has happened already is likely to happen again. Adhesions may be too strong and extensive to make removal prudent, the tumor may be other than ovarian, or it may be that no tumor can be found. Regarded in this light, it appears that the operation has been undertaken sixty-nine times, and that in thirty instances the patient has recovered after the extirpation of the tumor. It is true that forty-three patients survived gastrotomy; but many of them were subjected to such a painful operation, on the one hand, without necessity, and, on the other, without being dis embarrassed of the disease.

Two different plans have been followed in the operation; and it is proper to ascertain whether there has been a corresponding difference in the results. In the one plan, the incision of the abdominal parietes is sufficiently extensive to admit of the removal of the tumor entire; often extending from the ensiform cartilage to the pubis. In the other plan, the incision has had the extent necessary for the removal of so much of the tumor as would not escape through a puncture or incision made in it before the extraction was attempted. If the tumor contains little or no solid matter, a puncture might cause the complete evacuation of the contents, and the cyst might be removed through a very small opening. The author thinks the evacuation before extraction, and not the exact length of the incision, the important distinction between the two operations.

The principle of extraction entire has been followed in forty-four instances: the instances of successful removal by this plan amount to eighteen. The cases in which the plan of procuring the evacuation of as much as was practicable of the contents of the tumor before the extraction of the tumor was attempted, amount to twenty-five; the instances of success to twelve.

The evidence is, then, directed to the consideration of the following points:—1st.

Can we determine with certainty whether a tumor be ovarian or not? If not, have the failures been so frequent as to constitute a reason why the operation should not be attempted?

2d. Supposing a tumor to exist, and to be ovarian, can we ascertain the nature of its contents, as well as its connections? If not, have the failures been so many as to be an objection to the adoption of the operation at all?

3d. Are the results of this plan of treatment sufficiently favourable to justify us in preferring extirpation to any other mode of treating ovarian tumors? If so, what plan of operation promises most success?

The general materials, together with the circumstance that the author has been present, either as principal or assistant, in six of the operations, have given him peculiar facilities for fairly considering those questions; and the conclusions he comes to are, that we have not the means of determining with absolute certainty whether a tumor be an ovarian cyst or not (though he thinks the chances of error ought not to be so large as is represented by the tables); that we have no sure means of ascertaining the contents and connections of tumors presumed to be ovarian. After an elaborate consideration of the third question, he says, "the aspect in which the question should be ultimately regarded is this—the circumstances of the patient's case are so pressing that relief must be afforded; and, as all other means have failed, it must be by an operation. Tapping is usually a successful operation; so far, at least, as to afford immediate relief; and, in an ordinary case, the patient may reasonably expect to live four or five years; not in comfort, it is true, but requiring relief three, four, or more times, it may be, in a year. Extraction, though not a very painful, is a dangerous operation: the experience we possess justifies us in the expectation, that in at least forty-three cases out of every hundred the tumor may be extracted, and life saved; but at the same time it must not be concealed, that out of the sixty-nine operations to which reference is made, twenty-six died, and that soon—in fact, in a few days.

If the results already stated should be held to justify the performance of the operation of extraction in cases of ovarian tumors, it is incumbent upon us to select the operation which is least painful and perilous to the patient. It must be borne in mind that the plan of making such an incision as would admit of the extraction entire was employed in forty-four cases, and that the recoveries after extraction amount to eighteen cases. The plan of making such an incision as would admit of the extraction, when as much as possible of the contents were removed, was

followed in twenty-five cases, of which twelve recovered after extraction. The proportion of recoveries being in the one case 43, and in the other 48 per cent. The author's own experience is much more favourable, being five out of six.

It is evident, therefore, that the preponderance of success is in favour of what is termed the minor operation, that is to say, an operation in which the incision is as small as is consistent with the easy removal of an inflated cyst, provided it be large enough for the convenient application of the ligature around the pedicle.

Dr. Moore commenced the discussion on the last paper, which was the only one read at the last meeting for the season of the Society, by stating the necessity which existed for distinguishing the various kinds of ovarian tumors. Experience had made him familiar with at least three: 1st, where the ovary itself became converted into a cyst containing a simple watery fluid; 2dly, where the Graafian vesicles underwent degeneration, and became cysts filled with a thick, yellow, tenacious secretion; and 3dly, where a cyst was formed, not in the ovary itself, but in the adjoining peritoneal tissue, and which was the seat of those various coloured matters which were occasionally withdrawn from ovarian tumors by paracentesis. The first kind formed the cases peculiarly adapted for the operation of extirpation. He deprecated at some length the opinions expressed in the Society on a late occasion against the reception of this among the number of recognised surgical operations, believing that it would not be more fatal than lithotomy and many other admitted operations. From the paper he thought the eventual success of operations for extirpating the ovary was already shown to be more satisfactory than those practised by surgeons for diseases of the kindred organ, the mamma, the diseases of which, as far as his experience had shown him, always returned after the operation, and proved fatal.

Mr. Brown (a visitor) dissented from Mr. Phillips's statement of the utter inefficacy of therapeutical remedies in ovarian disease. He had himself succeeded in four cases by mercury carried to slight salivation, diuretics and tonics, and compression of the tumor combined with tapping. He had a fifth case under treatment, which he was certain would ultimately get well. Absorption had commenced, and the tumor had already lessened three or four inches. He had read these cases before the Physical Society of Guy's Hospital, and both the cases and the mode of treatment would be found described in the *Lancet* of May last.

Mr. Frederick Hale Thompson was astonished to hear the opinions expressed by the last speaker. How could any action

of the absorbents carry off such a thick yellow secretion furnished by such an extended secreting surface as that of the tumor, and one supplied by an artery as large as his little finger, and capable of pouring out such an immense amount of secretion? He warmly advocated the operation of extirpation of the ovary, but stated that it had not yet been performed at any hospital except Guy's. Indeed, he believed the operation was not adapted for hospital practice, because such institutions were unable to command attention to those numerous minute circumstances, amongst which was the preservation of an elevated temperature during and after the operation, and which was essential to its success.

Mr. Davies, of Hampstead, did not understand, and should like to know more about, the cases of incision which had been practised where no tumor existed, and those of dry tapping, and tapping for hysterical tympanitis, alluded to by Mr. Phillips. To his mind such occurrences were quite incomprehensible.

Dr. Theophilus Thompson complimented Mr. Phillips for the extensive research which his paper displayed, but would like to be informed, as some of the cases quoted were operated on so far back as 1816, what had been the result in those instances.

Mr. Coulson would also like to inquire whether age had exerted any, and what, influence over the results of the operation.

Mr. Phillips stated, that he was not prepared to occupy the time of the Society by going over such letters as might be found in the paper, but that he should confine himself to answering the several questions put by preceding speakers. He had no intention of considering the pathology of ovarian disease; his observations had reference only to treatment. He had no doubt Mr. Brown was a firm believer in the efficacy of the plan of treatment which he proposed, but so were many other advocates of particular plans; and there were none of those plans which did not number cures; but still they were abandoned; and why? because they seemed only to succeed in the hands of their inventors. Compression has been tried and had failed, even when associated with mercury; but then, says Mr. Brown, my exact combination of means was not employed: this may be so, but I am not sanguine enough to anticipate a different result even when the exact plan, as specified by Mr. Brown, is followed. Dr. Thompson asks whether we can give any account of the patients some years after operation? I fear not. The earlier operations were those of Macdowell, and we have no after history of the cases. The same may be said of those of Lizars, and indeed of most others; the bulk of the cases have been done within a comparatively recent period.

Mr. Davies is surprised that any one should cut open the abdomen without finding a tumor; so was he (Mr. Phillips), but nevertheless it is a fact that it has been done. In Mr. Lizars' case it is said a prominent sacrum induced the error; in other cases tympanitis seems to have caused the mistake. Mr. Coulson's question as to age is solved in the paper: the majority of cases have occurred between twenty and forty, but they occur earlier and later. Meyer mentions a case where the disease was congenital. Mr. Key conceives that young subjects have about them something unfavourable to this operation, but the results scarcely bear him out in his opinion. With respect to Mr. Thompson's idea of the necessity of an elevated temperature to ensure success, and to the impossibility of obtaining this in an hospital, it may be observed, that in many successful cases no such attention to temperature appears to have been paid; and in the case of hernia operations this is not regarded as a *sine qua non*. Besides, even if it be not desirable to operate in a spacious ward or theatre, there are usually to be found small wards in which no difficulty could be experienced in obtaining an elevated temperature. And, somehow or other, it happened, that people were better satisfied to accept an operation established in hospital practice, than one done in obscure corners on which the light of day did not shine.

The President remarked that Dr. Frederick Bird was present, and invited him to address the Society.

Dr. F. Bird would not enter upon the whole question of the operation, but, with reference to the statistics of the author, he must object to his comprising cases where the operation of incision had revealed no tumor, cases where the tumor was incapable of removal, and cases where it had been removed, in one common class. With reference to Mr. Brown's cases, he could assure that gentleman that he had strictly followed his method of treatment in five cases without the least benefit, and in one with apparent disadvantage; that to many competent judges the cases in Mr. Brown's paper were unsatisfactory, except one, in which a sufficient interval had not yet elapsed to justify the cure being regarded as permanent. As, however, the paper had been already read, and the views of treatment discussed at two societies, and the paper itself was now printed, he did not feel authorised in saying more in this Society upon it. With reference to the operation, he himself adopted neither the minor nor the major operation, strictly so called, but one in which the incision was of a medium length, to avoid the evils of irritation from unnecessary manipulation in the very small, and of unnecessary shock to the system by the very

large incision. He knew that many unfavourable cases had been suppressed by the operators. He considered the statistics of the author amply testified the superiority of the minor incision, but questioned the value of any other result derived from them. The high temperature he regarded as prophylactic against peritoneal inflammation, the main danger of the operation.

Mr. Phillips, in answer to Dr. Bird's objection, that in the paper all cases were classed together, whether a tumor were found or not, and extracted or not, rose and said he had heard nothing to induce him to think that course incorrect. If the abdomen had been laid open several times, and no tumor found—and we had the history of five or six such cases—and he was not sure that if we knew all, the number might be twice as many—he was bound to regard that as a thing which might happen again—as one of the evils with which the operation was beset. If again it was true that contrary to the impression at starting, in fourteen or fifteen cases the operation could not be completed, was it not fair and proper to regard that as another evil which in the present state of our knowledge attaches to the question? Who will now say, then, that, in estimating the value of this plan of treatment, the fair, the honest way of dealing with the question, is not to ascertain, as far as the honest dealing of our professional brethren will enable us to do so, in how many instances the operation has been undertaken, and in how many instances it has been successful?

UNIVERSITY COLLEGE HOSPITAL.

CLINICAL PRIZE REPORTS,

By H. FEARNSIDE, M.B.

CASE I.—Cancer of the pylorus—Dilatation of the stomach—Cancer of the peritoneum and ovaries—Ascites—Atrophy of the heart, liver, and spleen—Degenerated tuberculous matter in the apices of the lungs.

ANN BUTLER, æt. 50, admitted into University College Hospital, under Dr. Taylor, April 25, 1843. A woman of moderate stature, and rather slender conformation; she was never very robust, and has been especially delicate since she began to have a family; when young, she was occupied as a domestic servant, but for several years past her employment has been that of a charwoman. She has resided in London for thirty years, and during the greater part of this period in a rather densely inhabited and damp situation. For some time past she has been compelled by the circumstances of her family to undergo considerable priva-

tions, having often been able to obtain but a scanty supply of food; and from the same cause she has been obliged to exert herself much more than formerly: this has been the case principally during the last two years. Her father died of consumption; her mother in childbed. She is married, has had five children, and has miscarried four times: as a consequence of these latter occurrences, she was much debilitated for a considerable time; but, with these exceptions, although never strong, she appears to have generally enjoyed a tolerable amount of health. She has never since her childhood suffered from any acute disease; but during the last two years her strength has been failing, and she has experienced many of the common symptoms of dyspepsia, such as flatulence, variable appetite, and a sense of weight and oppression in the region of the stomach after taking food. About four months ago, after a hard day's work, or unusual exposure to cold, &c. she began to suffer from severe pain in the limbs, which was not, however, accompanied by any swelling or redness of the joints, heat of skin, or other febrile symptoms. She was attacked with pain in the upper part of the abdomen, and especially around the umbilicus, about a month ago, having continued to attend to her occupations until this time: her bowels became constipated; she had pain in the head, and a feeling of great prostration of strength: these symptoms supervened after being employed for a day in a damp room, and were succeeded in a few hours by vomiting. The constipation was removed for the time by repeated doses of purgative medicines, but the bowels have since again become exceedingly torpid; the vomiting has continued almost uninterruptedly to the present time, generally occurring about three or four hours after a meal; sometimes, however, she has not vomited until near the close of the day, and her stomach has then rejected food taken at various times during the day, and generally but little changed; she has also frequently vomited a dark brown fluid. About three weeks ago her abdomen rather suddenly began to enlarge, and this was attended with an increase of the pain around the umbilicus; it had been preceded by a diminution in the quantity of urine voided daily, as well as by constipation; and after the removal of the latter state it became less considerable, but it has continued in a greater or less degree up to the present time. She has failed much both in flesh and strength during the last month, but she has not lost her appetite in a proportionate degree.

Symptoms on admission.—The surface is moderately warm, and the hands moist, but the extremities are generally cold; there is no œdema of any part. The complexion is

of a somewhat dingy sallow hue; the cheeks are hollow; the eyes large and projecting; there is great prostration of strength, so that she is unable to stand unsupported; she has no pain in the head, but feels giddy on sitting up; she obtains but little sleep. She has no pain about the chest, cough, or dyspnoea; her breathing is tranquil, and the number of respirations 16 per minute.

Physical signs.—There is no difference in the movements of the two sides of the chest, nor in the vocal fremitus; the right post-clavicular fossa is less resonant on percussion than the left one, the sounds elicited on both sides being less clear than in health; the upper and anterior part of the right side of the chest is duller than the corresponding part of the opposite side, the difference being more obvious on percussion over the second rib than immediately below the clavicle. The lateral surfaces of the chest give out a clear sound on percussion; posteriorly there is marked dullness on percussion over the supra-spinous fossa of the right side, that of the left side being less resonant than natural. The same defect of pulmonary resonance is observed over the right lower scapular region; there is but little difference between the two sides on percussion over the inter-scapular regions; inferiorly, both sides sound nearly alike, and clearer than the upper parts of the chest. The breath-sound in expiration is more audible over the upper and anterior part of the right side of the chest than in health; the respiratory murmur is feebler about the second rib on the right side than on the corresponding part of the left side; over the right supra-spinous fossa respiration is feeble, and weaker than upon the left side; over the lower scapular regions respiration is also feeble, and on the right side occasionally bronchial; below the scapulae the respiration is loud and distinct on both sides. The sounds of the heart are faint; pulse 80, rather jerking, but compressible.

The tongue is rather red at the tip, and some papillae on its margins are florid and elevated; posteriorly it is covered with a pale thin fur. She complains of a constant saltish taste in the mouth; she has no thirst, and not much appetite; the vomiting still continues, and occurs generally three or four hours after taking food; the fluid portion of the ejected matters has a chocolate-like colour, and a strongly acid reaction. There is considerable tenderness on pressure over the epigastric region, especially towards its right side, but no tumor can be distinctly recognised; she can take hot food or liquids without any uneasiness; the bowels are open.

The abdomen is considerably enlarged, especially in its upper part; the swelling is of a somewhat globular form, and termi-

nates very abruptly a little below the umbilicus, and in a line inclining from this point towards the right iliac region. The sound on percussion over the anterior part of the abdomen, as the patient lies upon her back, is tympanitic, but over the flanks there is decided dullness, which, however, disappears in a great measure on firmly pressing the percussed finger against the abdominal walls. When the patient lies upon one side the sound on percussion over the opposite side is then clear, whilst over the most depending parts it is dull; moreover, fluctuation is distinctly perceptible to the hand.

The liver does not extend for the space of an inch below the margin of the ribs, nor does it appear to rise into the chest (as indicated by percussion) beyond the lower border of the sixth rib. The urine is scanty, slightly acid, sp. gr. 1026, and it appears to contain a slight excess of the phosphates. The catamenia have not been present for the last four months.

Treatment and subsequent progress of the case.—Small doses of hydrocyanic acid, and of the tincture of the sesquichloride of iron, were prescribed to allay the vomiting; and as the patient complained of inability to sleep, a quarter of a grain of hydrochlorate of morphia was directed to be taken every night. A small dose of castor oil was given soon after the patient's admission, and subsequently repeated as circumstances required. Her diet at first consisted principally of arrow root, but, on account of her great debility, she was afterwards allowed animal food and wine. Under this treatment the vomiting completely ceased in about five days, and the tongue became clean; she slept better, the enlargement of the abdomen diminished, and the pulse acquired more power. This apparent improvement was interrupted on May 3d, by a return of the vomiting, and the fluid ejected from the stomach was described as being of a blackish colour. For some days after this time, the most prominent feature in the case was the great prostration of strength which existed. On May 8th, she suffered much from pain in the upper part of the abdomen; this was relieved by a dose of morphia and warm fomentations. She continued gradually sinking from this time. The pulse was usually about 60 per minute, and the number of respirations 12 or 14. She complained frequently of a sense of coldness; she was frequently affected with giddiness,—and as it was supposed that this might be referrible to the morphia, that remedy was discontinued; she had no return of the vomiting until immediately before her death, which took place on May 16th; and she only suffered occasionally from pain in the abdomen, which was rarely acute and

lancinating, but more generally of a dull, heavy character.

Examination of the body 26 hours after death.—*Exterior*: The body was extremely emaciated; there were a number of spots of purpura upon the lower part of the front of the thorax, and anterior parts of the thighs.

Head.—The membranes of the brain appeared healthy; there was rather more serum than usual beneath them; the substance of the brain was uniformly soft and pale, and contained less fluid than usual. Weight of the brain, 2lb. 11½oz.

Chest.—There were a few ounces of bloody serum in each pleural sac; there were a few slight adhesions between the costal and pulmonary pleura, over the apex of the left lung. The lungs generally were of the full size, dark coloured, and mottled over with black spots. The apex of the *left lung* was indurated, rather puckered, and contained some soft cretaceous, or putty-like matter: the pulmonary tissue in the vicinity of this part was dark coloured, dry, and dense. The substance of the upper lobe of the lung was throughout dark coloured; it contained but little fluid, and was less crepitating than usual. The posterior part of the lower lobe was uniformly dark coloured externally; the tissue of this part was dense, contained a considerable quantity of serosity, and not much air, and did not readily give way to pressure. Weight of the lung 13 oz.

The *right lung* was rather paler than the left one; its substance was more puckered and corrugated than the corresponding part of the opposite lung; there was a small cavity about an inch below the apex (corresponding to the principal seat of dulness on percussion during life), lined by a yet distinct membrane, and containing putty-like matter. The greater part of the upper lobe contained but little fluid, and resembled the upper lobe of the left lung. The lower lobe was posteriorly of a dark colour, dense, and contained much serosity. The mucous membrane of the bronchial tubes in both lungs was rather pale. Weight of the lung 14 oz.

The *heart* was small, weighing only 4 oz.; its vertical measurement, in particular, appeared short; there was a white patch on the right ventricle, and another on the apex of the left ventricle; the tissue of the latter part was dry, and of a brown colour; its walls measured seven lines in thickness at the base; its cavity was small, and the lining membrane healthy; the aortic valves slightly thickened. The walls of the right ventricle were about a line and a half in thickness at the base; the tricuspid orifice was large, its valves healthy. The lining membrane of the aorta was raised by an opaque yellow deposit beneath it, some portions of which were osseous. The blood

contained in the cavities of the heart was thin, dark coloured, and fluid.

Abdomen.—The *stomach* was much enlarged, being at least three times its natural size; it extended across the upper part of the abdomen, from above downwards, and from left to right: its longest diameter measured twelve inches: it contained much undigested food, and in its contents were a number of fruit stones; its coats were pale. Near the pylorus the mucous membrane was mamillated; and beneath it, at one part, there was a quantity of gelatinous matter. The muscular coat at the pylorus was about a line in thickness, and external to it there was a quantity of dense, whitish, semi-transparent tissue, surrounding and constricting the pyloric aperture; so that the point of the little finger could with difficulty be introduced into it. No milky fluid could be expressed from the adventitious deposit; but subsequent microscopic examination proved it to be distinctly scirrhus. The mucous membrane was ulcerated at one small spot only.

The *duodenum* was enlarged, equalling in volume the large intestine; its coats were rather thickened; the lining membrane somewhat discoloured, being of a greenish hue, which, however, readily disappeared under slight friction. The calibre of the other small intestines was diminished, and the mucous membrane generally pale. The large intestines were less capacious than usual; the mucous membrane of the colon was soft; the mesenteric glands were not enlarged.

The *peritoneum* generally, both parietal and omental, was studded over with small semi-transparent granular prominences, of about the size of pins' heads; their nature was afterwards determined, by microscopic examination, as scirrhus. The peritoneal sac contained two or three pints of yellowish serum.

The *liver* was small, its antero-posterior diameter measuring only five inches; it was of a uniform dark colour, and in a state of incipient cirrhosis. The portal canals in many parts were surrounded by a considerable quantity of dense cellular tissue. The gall bladder was of ordinary size, and contained some thin yellow bile. Weight of the liver 2lb. 4½oz.

The *spleen* was exceedingly small and firm; weight 1 oz. The *pancreas* was healthy.

The *right kidney* appeared large; its capsule was thickened, and rather firmly adherent to the parenchyma of the organ, portions of which were removed on separating the capsule. The surface of the kidney was dark coloured; its tissue was firm. Weight 4 oz.

The capsule of the *left kidney* was less

firmly adherent than that of the right one; the substance of the organ was very firm. Weight 3 oz.

The ovaries were much enlarged, corrugated, and hard. On a section being made the cut surfaces presented a dull white appearance; a number of vascular points were also perceptible.

The os uteri was roughened, little projections of the size of pins' heads existing upon it; it was dark coloured, but not ulcerated. A considerable quantity of white adventitious matter existed in the walls of the uterus.

REMARKS.—The disease in this case was evidently of a serious character, and of some duration; the emaciation present was such as is not witnessed in acute diseases, and its extreme degree was in itself a reason for suspecting the existence of some disease of the digestive organs, and especially of the stomach. That the disease was a chronic one, was proved by the history of the case, as well as by the absence of any febrile symptoms.

The existence of vomiting was an additional reason for supposing that the stomach was the organ implicated; and the occurrence of this symptom regularly, for a considerable time, at a period of some hours after the food had been taken, appeared to point out that the outlet of the organ was the part (principally, at any rate) attacked. Another circumstance confirming the same view was the fact of vomiting sometimes taking place in the evening,—the ejecta then consisting of food taken at different times during the day.

Again, the characters of the matter vomited,—the almost unaltered food, and the dark-brown strongly acid fluid, served to give strength to the opinion that there was some severe organic disease of the stomach. But there was an absence of any perfectly characteristic signs; the existence of any tumor in the epigastric region was never satisfactorily determined. All the symptoms present might occur equally in a case of chronic gastritis with ulceration, or in one of carcinoma of the stomach. In the absence of any perceptible tumor, M. Andral states that "there exists no sign by which we are able to distinguish, what we designate, in common medical language, a cancer of the stomach, from a case of chronic gastritis."

The somewhat sallow hue of the patient's complexion, her age, the nature of what appeared to be the cause of the disease, (excessive exertion, a defective supply of food, and anxiety of mind), were in favour of the opinion that the disease of the stomach was cancerous.

In addition to the gastric lesion, there was

also an accumulation of fluid in the peritoneal sac. On first examining the case, Dr. Taylor stated that the symptoms might be owing to cirrhosis of the liver, which was evidently below the average size; or, supposing the disease of the stomach to be cancer of the pylorus, they might be occasioned by the same malignant disease having attacked the peritoneum; a considerable part of the enlargement of the abdomen, however, was obviously due to tympanitic distension of some of the hollow viscera. The physical signs derived from an examination of the chest gave evidence of the existence of condensation in the upper parts of both lungs, and of the right one in particular; and the marked dullness on percussion upon the second rib on the right side, showed that the alteration in density was rather below the apex of the lung. Supposing the disease of the stomach to be cancer, and taking into consideration the rarity of the simultaneous existence of cancer and tubercle, it was thought not improbable that the consolidation might be owing to carcinomatous deposit in the lungs.

The earliest symptoms presented in this case were simply those of ordinary dyspepsia, *e. g.* a sense of oppression in the epigastric region after taking food, flatulence, &c. No attention seems to have been paid to these symptoms for some time, and the patient's health and strength, although inferior to what they had previously been, and gradually failing, were still equal to a considerable amount of physical exertion, until about a month before her admission into the hospital. About this time she began to suffer from other symptoms of gastric disease; vomiting supervened, and for some time the stomach appears to have rejected almost every meal, but little chyme being allowed to pass the pylorus, the natural consequence of which was great and rapidly produced emaciation. It thus appears probable, that the disease had been going on for some time, without giving rise to any other symptoms than such as are presented in common functional disturbances of the stomach—a circumstance repeatedly observed in other examples of this disease. An opinion has been entertained, that in many at least of such instances, the absence of symptoms might be attributed to the disease being located in the smaller curvature of the stomach, or near the pyloric aperture, thus leaving the larger extremity of the organ free to exercise its peculiar functions. The proper office of the stomach, in reducing the various articles taken as food to a uniform pulp, appeared to be completely unimpaired in the present case, as they were rejected before ever being swallowed, with their original characters but little altered.

In the progress of the case the most important symptoms were those indicating the existence of obstruction to the exit of the food from the stomach, which failing in its attempts to expel its contents by the natural outlet, becomes irritated, and vomiting ensues at a longer or shorter period after food has been taken. But the vomiting would appear to be due, not merely to the obstruction presented at the pyloric aperture, but the state of the organ generally. One of the most frequent conditions cooperating with the obstruction in giving rise to vomiting, is probably a state of congestion, or exalted sensibility of the mucous membrane. Such, it is not unreasonable to suppose, existed in the present instance, for, after the use of sedatives for some time, the vomiting ceased, and only returned at occasional and distant intervals.

The pain which the patient experienced had but little of the lancinating character usually ascribed to carcinomatous affections of the stomach; it was generally described as a sense of uneasiness, with occasionally a dull, heavy dragging pain in the upper part of the abdomen.

The state of the tongue is worthy of a passing remark; it was usually clean, or but slightly furred,—proving the truth of the observation, originally made by Louis and Andral, that the tongue is less an index of the state of the stomach than of the system generally. A symptom from which the patient seemed to experience much annoyance was the constant saline taste in the mouth, as if the excess of acid in the gastric secretion left a proportionately large quantity of alkali to be eliminated by other channels.

[Want of space compels us to defer some of the remarks on this interesting case.—Ed.]

HYDROPATHY—HOMŒOPATHY.

THE existence of hydropathic institutions—those dens of covetous and rapacious gamblers—where the wretched invalid resorts to throw the dice for health and life; the rise and progress of the homœopathic system, which treats truth with scorn, and bids defiance to common sense, loudly proclaim the need which exists for the adoption of settled principles, definite methods of research, and a systematic arrangement to guarantee their attainment and retention [in the practice of medicine].—*Liebig, in Lancet of June 29th.*

APPENDIX TO A PAPER
ON THE
SPECIAL FUNCTION OF THE SKIN,*
PATHOLOGY OF FEVER; TREATMENT
OF SCARLATINA; CAUSES OF
ALBUMINURIA.

BY ROBERT WILLIS, M.D.

M. FOURCAULT made what may probably be viewed as the most remarkable physiological observation of the age, viz. that an animal, healthy and uninjured, very soon dies if its body be covered with an impervious glaze. Becquerel and Breschet, repeating the experiment of M. Fourcault, discovered that the extinction of life under the circumstances indicated was accompanied by a signal fall of temperature: the animal whose body was endued with an impervious glaze began to lose heat on the instant; and the loss never ceased until life had fled, when the temperature of the internal as well as external parts of the body was found to be within 3° Cent. of that of the external atmosphere, which on the day of the experiment indicated 17° C.

Neither M. Fourcault, nor MM. Becquerel and Breschet, offered any explanation of the remarkable phenomena they observed; these appear, from their silence, to have been altogether enigmatical to them. MM. Becquerel and Breschet only see that the old office of the cutaneous exhalation, as a means of refrigerating the body, was gone. Here was the exhalation completely suppressed, and the temperature of the body, instead of rising, as it ought to have done, began at once to sink, and went on sinking till life was extinct, when it was but three degrees Cent. higher than the temperature of the surrounding atmosphere.

In a paper which I had the honour of submitting to the Royal Society in the

month of December, 1842, and which was read before that illustrious body on the 2d of March, 1843, I ventured on an explanation of the phenomena observed by M. Fourcault and MM. Becquerel and Breschet. An abstract of this paper was published in the Proceedings of the Royal Society in the second week in April, 1843. The purport of that paper being physiological, I had not at first intended to do more than hint at the practical application of the views which it embodied. But as a very brief survey in this direction seemed calculated to present these views in the same interesting and important bearing in which they met me, I appended a somewhat long note to supply what I conceived to be a deficiency in my communication.

It is only, indeed, when the function of the skin comes to be regarded as so intimately connected with vital manifestation, as it unquestionably is, that we are enabled to understand wherefore such serious consequences should follow its derangements. Suppressions of the cutaneous exhalation under the agency of cold, is the acknowledged cause of the greater number of the diseases to which the inhabitants of temperate countries are subject. But we have no satisfactory explanation of the way in which cold exerts its pernicious influence, or of the manner in which consequences are here linked with their presumed cause. Without entering into the explanations that have been given of this matter, I shall merely say that in my mode of considering it, he who has suffered a *chill* has had the secreting faculty of his skin deranged or suppressed, and physiologically speaking is brought into the same condition as he would were his body more or less perfectly covered with an impervious varnish. A process indispensable to the continuance of vital action has been interfered with, and disturbance of the general health, commensurate in amount with that of the particular functional disturbance mentioned, forthwith ensues. The injury mentioned in this in-

* Vide MEDICAL GAZETTE of April 5th, 1844.
867.—XXXIV.

stance may possibly partake in its essence of the nature of inflammation. When we have the web of a frog's foot under the microscope, and prick the part with a fine needle, instantly all movement around the injured part is arrested: the blood stagnates in its channels, which dilate visibly, and by and by the several blood-corpuscles run together and form aggregated masses. The explanation of this that has been suggested is simple and satisfactory: the local injury impresses the precipient centres in a way which incapacitates them from transmitting the usual stimulus upon which depends the tone of the living tissues; these are consequently paralysed, upon which follow stasis of the blood in the blood-vessels, and all the consequent phenomena of inflammation. But the influence of cold extensively applied to the cutaneous surface is probably little different from that of other stimuli acknowledged to be efficient causes of inflammation. The effect on the peripheral nerves has a paralyzing influence upon the excitomotor system for its consequence, and connected with this are suspended function, and more local or more general derangement,—in a word, disease. In this way can I render to my own mind a satisfactory account of the influence of cold in the production of disease, not only in all the colder and more temperate, but also in the hotter regions of the earth.

The problem of highest interest in medical science that waits for solution at the present moment, is perhaps this:—*To explain the cause of the unhealthiness of so many tropical climates, and of alluvial and marshy countries generally, where the summer temperature is high.*

A particular specific contagion, designated *miasm* or *malaria*, it is familiarly known, has been imagined and is very commonly admitted as a means of accounting for the deadly fevers in especial which there prevail. But after a very careful study of the subject, I am bound to say that I entirely concur with those who, from their experience in tropical climates, have felt themselves authorized to deny the existence of any specific contagion or miasm, the product of vegetable matters in a state of decay under the combined influence of heat and moisture. As chemists, we are perfectly familiar with the products of the decomposition of vegetable substances under such circumstances, and as physiologists with the effects of the gases then evolved upon the animal economy, which certainly bear no resemblance to the phenomena of remittent and intermittent fever. According to my ideas, marsh, miasm, and malaria, are nothing more nor less than *moist warm air*.—*air, excessively moist considered in connexion with its own temperature, and the temperature of the human body.*

It is comparatively easy, as is well known, to remain for a certain time in a stove-room of a temperature considerably higher than the body, *if the air be dry*. Here there is free elimination of watery vapour by the sudoriparous glands, and even as rapid solution of it by the parching air. The capillary arteries then exude, and the veins imbibe with great rapidity, so that the nutritive or vital acts are even performed with a kind of increased energy. They are so performed, however, only for a short time: excitement soon begets exhaustion, the body rises in temperature, and death is the necessary consequence of protracted continuance in the circumstances indicated.

The consequence is the same, but the way in which it is brought about is different, when *the air of the stove-room is moist*. M. Delaroche, in his second set of experiments, in which moist instead of dry air was employed, ascertained that temperatures a degree or two Centigrade short of those, or just equal to those, of the animals which were the subjects of experiment, were felt as more speedily detrimental, and then fatal, than the excessively high temperatures with dry air, which he had already approved. Wherefore this should be the case will be readily understood in connection with the views which I have taken of the function of the skin. In a hot, dry atmosphere, animals perish from the effects of excitement; in a warm, moist air, of a temperature no higher than that of their own bodies, they die as they do when covered with an impervious glass—the conditions requisite to the access of oxidized plasma, and the removal of deoxidized plasma, are wanting, and life ceases as a matter of course.

Now it is highly interesting to observe that the air of unhealthy intertropical climates differs little from that of a vapour-bath at between 80° and 90° Fahr. The dew-point of the atmosphere in these countries appears, in general, to be not more than four or five degrees, and frequently not more than a single degree, Fahrenheit, below the temperature of the ambient air. Were the temperature between 90° and 100° Fahr., and the dew-point in the same proportion high, man could not by his nature continue to exist for more than a very few hours. In a country having a high mean temperature, say of about 80° F., and an atmosphere that is close upon the point of saturation with humidity, which is precisely what obtains on the western coast of Africa, to quote a single instance, man is evidently on the verge of circumstances that are even incompatible with his existence*. He has

* The best and most complete set of meteorological observations on the atmosphere of the Coast of Africa, with which I am acquainted, are those appended to Dr. Pritchett's account of the

but to be exposed to fatigue and the burning rays of the sun to be actually brought into such circumstances. The surrounding atmosphere cannot take up the watery vapour, which is then presented to it in large quantity by the sudoriparous glands, with sufficient rapidity to meet the wants of the system in its state of excitement, and requiring the freest access of the most thoroughly oxygenated plasma to keep up movement and life in its several constituent atoms. Great general derangement—*Fever*—ensues, and life is almost of necessity the forfeit.

I have no doubt but that the simple excitement which follows exposure to the sun's heat, in connection with the humidity of the atmosphere, will be found to explain what has been spoken of by writers on the diseases of tropical countries under the title of *solar influence*, by which they understand a certain mysterious and maleficent power emanating from the sun, and distinct from his light and heat. . . With the view which has just been given of the function of the skin, all that was mysterious and unintelligible in the doctrines of malaria and solar influence disappears, or merges into what is perfectly natural and comprehensible.

The *lunar influence*, in like manner—for some have thought that there was a peculiar maleficent influence in the moon as well as in the sun—will come to be nothing more than the effects of the relatively increased moistness of the air which follows the fall in the temperature of the night season: the air loses several degrees of heat, and in the same, or nearly the same proportion, it gains in degrees of moistness; growing relatively to its temperature more and more humid, it is soon in the state in which it can not only dissolve no more watery vapour, but in which it begins to deposit what is already held in solution: hence the heavy dews of unhealthy intertropical climates, and of marshy temperate countries generally, and the deleterious effects which exposure to the night air produces upon the frame of man. The rapidity with which moist air even of 68° or 70° F. abstracts heat from the body, must also be taken into the account. It is very easy to have a decided chill as the first element in the derangement, i. e. in the fever, which is so apt to ensue under such circumstances. And then, if the remarkable fact, first ascertained by that admirable observer, Dr. Davy, be added, that under fa-

tigue the temperature of the body actually *falls*,—it does not rise, as the sensations seem to indicate,—it strikes me that we are no longer under the necessity of recurring to any unknown and hypothetical agent as the cause of the diseases which arise under exposure to atmospherical inclemencies, whether of heat or cold, especially when the exposure is conjoined with fatigue. On setting out on a journey in the Island of Ceylon, Dr. Davy ascertained the mean temperature of his palanqueen bearers to be 98·9° Fahr. under the tongue; on calling a halt at different times as he proceeded, he found it successively 98·6° and 98·5°; doubtless, had he pushed these men beyond their powers, their temperature would have fallen still lower, and, in all likelihood, he would have had them down in fever. Dr. Davy himself observes, in connection with this subject, on the instances of sudden death that have occurred from drinking cold water, or from plunging into cold water after exhausting fatigue, and when the body is commonly said to be heated. Probably, in such cases, in conformity with the above observations, the temperature of the body had been actually reduced below its natural standard, and the fatal effect may be the consequence. This, in fact, was the view that was taken by Currie, who, in his Reports, has collected many examples of the kind, and amongst them has quoted that interesting and impressive catastrophe which befel the army of Alexander the Great on the banks of the river Oxus, where, according to Quintus Curtius, the loss of life was actually greater than had been experienced in any single battle. The circumstances of the case were—a forced march of forty-six miles, in hot weather, over a desert; excessive thirst and exhaustion, and in this state drinking large draughts of cold water*.

The importance of the state of the skin in different diseases, in connection with their tendency, is well known to practitioners. What surgeon does not feel confident that his patient is going on favourably, after even the severest operation, if his skin but continue soft and velvety? and it is the same in almost all diseases. Some diseases I am inclined to think even prove fatal by inducing total suppression of the cutaneous exhalation; among the number, Scarlatina. Speaking generally, we may distinguish two fatal forms of this hitherto uncontrollable disease; one, in which the throat is very seriously implicated, and in which almost from the beginning typhoid symptoms are engrafted upon the originally frank inflammatory type of the disease. In this form

remittent fever which occurred during the late Niger expedition. The tables are full and extremely valuable; they not only show the state of the atmosphere in reference to temperature and moisture at three different hours of every day, for more than a year—May 1841 to June 1842—but even give hourly observations during an entire day at six different dates. Dr. Pritchett's work is not only highly creditable to him as a zealous physician, but as an excellent general observer.

* Vide Dr. Davy's Researches, Anatomical and Physiological, vol. i. p. 199.

the disease tends to destroy life less rapidly; it will run on for a fortnight or three weeks, and prove fatal at last by exhaustion, or the patient may make a slow recovery. The other form is that in which the disease exhibits itself with its usual acuteness—smart pain of the throat, great heat of surface, a very rapid pulse, but in which, from about the time when the disease attains its status, the patient begins to be drowsy; this drowsiness continues, increases; the pulse shrinks in size, but augments in frequency, till it can no longer be counted; the patient can be roused by shaking him or speaking loudly into his ear, but he immediately relapses into his lethargic state; alarm is taken; stimulants of all kinds—ammonia, ether, brandy—are had recourse to, to endeavour to keep up the flagging powers of life, but all in vain; the efflorescence assumes a dusky hue; the patient sinks lower and lower; he becomes thoroughly comatose, and cannot be roused; he has a slight convulsive attack, and expires. This is the form of scarlatina which occasionally proves so awfully fatal; against which medical art seems unavailing,—which sweeps off three, four, and even five members of the same family in the course of as many days, and, perchance, leaves the house childless, that, but a week before, seemed secure in its prospects of heirship and succession.

On making post-mortem examinations of the bodies of those who have fallen victims to this acute form of scarlatina, little or nothing is found amiss: the efflorescence has faded from the surface, some little suffusion of the mucous membrane of the fauces, some congestion of the brain, and a very small quantity of fluid in its ventricles—such is the catalogue of necroscopic appearances.

I have myself had more than one distressing opportunity of watching the disease destroy life in the way just mentioned; and it was only after having proved the usual practice in such circumstances nugatory, and having had my attention particularly directed to the physiology of the skin, that I was led to refer the fatal tendency of acute scarlatina, in its earliest stages, to suppression of the cutaneous exhalation, and, instead of resorting to stimulants to support the powers of life under this depression and drowsiness, to bend all my efforts to restore the function of the skin.

The means of accomplishing this are various. I have found a full emetic dose of ipecacuanha and tartrate of antimony suffice to interrupt the disposition to coma, which was effectually prevented from recurring afterwards by the ordinary diaphoretic mixture of acetate of ammonia and camphor julep, with fifteen or twenty minims of the antimonial wine, repeated at intervals.

A case that looks threatening as the disease is acquiring its status will often be rendered manageable and even mild by this simple means. Another very important measure is the reduction of the superficial temperature. The patient should be kept covered with a sheet, and have a sponge, dipped in tepid water, passed over every part of his body by the hour together, until the thermometer both in the axilla and mouth from 106° or 108° Fahr. has been brought down to 99° or 100° Fahr. This is the test that the application has been carried far enough and has been effectual. It was simply by reducing temperature and restoring the office of the skin, that the affusion of cold water, as recommended by Dr. Currie, cut short, or rather rendered safe and manageable, the acute forms of scarlatina in which he counselled it. This useful means, from its application not having been understood, has fallen into discredit with the regular practitioner. It might certainly be restored with advantage in many cases.

I am far, however, from maintaining that the means thus far indicated are the only means that would be indicated in every case of febrile disease. The first element in fever is perhaps even more commonly depression than excitement; it is pure excitement, the consequence of the inoculation of a specific morbid person, in scarlatina; in intermittent and continued fever I believe it always to be depression; so that the means of restoring the balance would be not the farther abstraction, but the addition of stimulus.

In a conversation which I had last summer with Mr. W. F. Daniell, who had at that time had ample experience in the diseases of Western Africa, and who is at this moment prosecuting his researches in that deadly country, he informed me that his conclusions from actual observation tallied exactly with my physiological inductions as to the cause and nature of the fever of intertropical countries. In a letter which he addressed to me on the 27th Sept. 1843, on the eve of his departure for Cape Coast Castle, and speaking of his purpose of publishing on the Diseases of Western Africa, he says: "I have stated the proximate cause of most African fevers to depend on an *impaired or deranged condition of the vital functions of the skin*, a definition which I imagine will be in conformity with your own views on the subject." It is always highly gratifying to find physiological inferences supported and borne out by practical observations, and I own that I look forward with much solicitude to Mr. Daniell's return to this country, and to the appearance of his work. Upon this occasion, I spoke to Mr. Daniell of a hot air bath as the likeliest means of cutting short a threatened attack of intermittent or remittent fever. He informed me that by directing

all his attention to the state of the skin he had been eminently successful in the treatment of the African remittent. Dr. Pritchett also observed that patients in the Niger expedition did best when they were kept somewhat warmly covered; sponging with cold water, and exposure, were always followed by dryness or parching of the skin, when the patients became uneasy and nervous.

[Since the preceding observations were written, M. Fourcault has still farther pursued his curious researches on the influence of the cutaneous envelope of the body and its function, which all tend to confirm and extend the conclusions come to: on covering the skin of a healthy animal with an impervious glaze, M. Fourcault finds that *albuminuria* is an invariable consequence in the dog, and a very frequent one in the rabbit. But the conclusions are so curious that they deserve to be made the subject of a special notice.]

REPORT
ON THE
ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the *London Medical Gazette*.)

[Continued from p. 464.]

DURING the year 1842, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2090 women—Of which cases,

20 were twins—one in every 104½ cases: of these in 10 both heads presented; in 8 the presentation was head and breech, or some part of the inferior extremities; and in 2 both were breech or inferior extremities. In 7 of these cases both children were boys; in 2 both girls; and in 11 of different sexes.

1076 children were males.

1034 children were females.

2068 were presentations of some part of the head, of which 4 were face presentations—one in 527½ births.

40 were presentations of the breech, or some part of the lower extremities—about one in every 52½ births; of these 12 were twins.

2 were transverse presentations, at full time; one in 105½ births. One of these children had lain dead in utero for three weeks; it was very putrid, and although a large child, was expelled doubled, or by what is called "the spon-

taneous evolution." It was a presentation of the right side, about mid-space between the axilla and the hip; the ribs being the part first touched by the finger. To the other case I was called on the 8th day after the membranes had broken. The left arm was external and much swollen, the head was high towards the right side, the face looking towards the spine, and the neck over the pelvic brim. Attempts had been made by the district surgeon to deliver by "turning," which had failed. The uterus was very strongly contracted, and the cuticle peeling off the child's body: the chest was too high to be perforated: I therefore passed my father's hook around the neck, and separated the head from the body without any difficulty. This was the woman's third child. I had delivered her by the same operation, after having exsuscated the fœtus, a year before. Both the women did well.

In 4 cases the placenta was implanted entirely over the os uteri—one in every 522½ cases. All these women were delivered by "turning;" all of the children were born still; one was putrid. Two of the women died of the effects of the hæmorrhage; one in two hours, the other on the sixth day.

11 were complicated with alarming hæmorrhage before delivery, not the result of placental presentation—one in every 190 cases. One of these was a case of premature twins; the woman had suffered a severe accident; another also arose from an accident at full time; three other cases were premature. Three only of these children were born living: in one case the placenta was adherent: in most the flooding was either stopped or much moderated by the artificial rupture of the membranes. All the women did well but one, who had lost an excessive quantity of blood suddenly; the child was turned; it was born dead, and the woman never rallied.

In 9 the placenta was retained within the uterus, either by atony or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—about one in every 232 cases. One was a breech case at 6 months. One woman died of irritative fever at the end of five weeks. The others did well.

3 were complicated with alarming hæmorrhage after the natural expulsion of the placenta—about one in every 697 cases. One was a case of twins. One woman died in four hours; she was 8 months advanced: she was suddenly frightened on the morning of the day on which she was delivered, and fainted: she did not feel the child after; labour came on immediately; the child was born dead; the uterus relaxed after it had expelled the child, and in spite of all the means used to induce contraction, remained flaccid till her death.

In 3 craniotomy was performed—about one in every 697 cases. In all these cases the pelvis was much distorted. The women all recovered.

1 was delivered by the short forceps; the child was dead. The woman recovered.

In 1 premature labour was induced solely by the use of the ergot. She was delivered in 20 hours after she began the medicine; the child was born alive, and was living in last May, a strong and hearty girl.

1 was complicated with puerperal convulsions, which came on while the head was pressing on the perineum; the child was expelled naturally, alive; she had one before its birth, and two after; she was much relieved by bleeding and purging, and did well. It was a primary labour.

1 was complicated with a ruptured uterus. It was the woman's 12th child; the feet presented; the uterus did not act violently, and I understand that no force was used in extraction; the child was dead, and the woman survived the birth only three hours. I did not see her.

1 was complicated with a longitudinal laceration, two inches in length, on the inside of the left labium, which took place as the child was being expelled through the pelvic outlet. I saw her six hours after her labour. The labium was then swollen to a size larger than a closed fist, very painful and livid; the cellular substance was filled with coagulated blood. I removed as much as would fill an ordinary tea-cup; and having satisfied myself that the ruptured vessel had ceased to bleed, ordered a poultice to be applied. On the fourth day the swelling had entirely, and the blackness had almost disappeared, and suppuration

had commenced; the cavity closed rapidly, and the part was perfectly healed considerably before the end of the month. The woman suffered very little in her general health.

11 women died either from puerperal causes, or within the puerperal month—one in every 190 cases; 10 only, however, from the effects of labour, for one died of pneumonia, which supervened on chronic disease of the lungs—being one in every 219 cases.

2041 children were born living.

69 children were born still—about one in every 30 births.

Of the Deaths,

2 were from hæmorrhage under placental presentation; one within two hours, the other on the sixth day.

1 was almost immediately after artificial delivery, under accidental hæmorrhage.

1 was four hours after delivery, from hæmorrhage which came on after the natural expulsion of the placenta.

1 from ruptured uterus, three hours after delivery, under a footling presentation.

1 from peritonitis, on the 7th day after premature delivery.

2 from hysteritis; one a fortnight after delivery, the other on the 10th day. She was as well as could be till the 6th day, when she had a quarrel with a neighbour, and put herself in a violent passion; she was soon seized with inflammatory disease, and lived only four days.

1 from irritative fever, five weeks after delivery, complicated with adherent placenta and hæmorrhage.

1 from sloughing of the vagina, six days after a lingering labour.

1 from pneumonia, which supervened upon chronic disease of the lungs, on the 6th day after delivery.

Of the still-born children,

23 were premature.

9 were putrid, at full time, or nearly so.

3 were breech presentations, at full time, or nearly so.

2 were transverse presentations at full time, or nearly so.

3 were delivered by craniotomy.

1 was delivered by the forceps.

4 were under lingering labour.

4 were delivered under placental presentation.

5 were under violent accidental hæmorrhage, at full time, or nearly so.

1 was under ruptured uterus.

3 were with the funis prolapsed; one by the side of the head; two by the breech: besides these the funis prolapsed by the side of the head in one other case; and the child was born living.

1 was where the funis was three times twisted round the neck.

10 were at full time, not putrid, nor delivered by art; there being no assignable cause to account for these deaths.

ON CERTAIN POINTS
IN THE
MECHANISM AND PHYSIOLOGY
OF THE
CIRCULATION OF THE BLOOD.

BY GEORGE ROBINSON,
Fellow of the Royal Medical and Chirurgical
Society, &c.

(For the London Medical Gazette.)

[Continued from p. 436.]

PART II.—*Of the mechanism of absorption; in which it is attempted to trace that action to the peculiar physical conditions regulating the passage of the blood into, and through, the veins.*

BEFORE mentioning the facts which appear to me calculated to illustrate the mechanism of the opposite function of absorption, it may be well briefly to review one or two of those opinions on the subject which have already been presented to the public.

I have previously had occasion to notice Magendie's general doctrine as to the transmitting power possessed by membranes; and have given some reasons for my disbelief in the sufficiency of that explanation of the various processes of exudation and absorption. The latter function, however, is by the same authority still more explicitly declared to depend upon an affinity of the vascular walls for the substances absorbed*. But while acknowledging the great value of many of the laws regulating animal absorption which have been established by the labours of this eminent physiologist, I cannot perceive that the experiments adduced in support of this particular doctrine do more than prove the porosity of membrane; for they appear mainly intended to

shew that the same interchange of fluids which takes place through inorganic porous septa, will, under similar circumstances, also occur through animal membrane. And as this power was by Magendie himself considered as but *one* of the probable causes of vascular absorption*, it still remains to discover what other physical conditions assist in the performance of this function.

There is another view of absorption, which as it, in name at least, bears some resemblance to that which I shall presently advance, requires a moment's examination. I allude to the opinion of the late Sir D. Barry. The experiments of this gentleman prove very satisfactorily, that during each act of inspiration there is a rush of venous blood into the imperfect vacuum then formed within the thoracic cavity. On introducing a long glass tube into the interior of certain large veins, he also found that a coloured liquid, into which the lower end of a glass tube dipped, ascended in the latter to the height of several inches during each inspiration, and fell during the opposite act of expiration.

This ascent of the coloured fluid he conceived to be an act of absorption rendered visible by the glass tube, the lower end of which represented the open mouths of the absorbing vessels†. In observing that the sanguiferous and lymphatic vessels have a similar communication between their extremities and the thorax, he has apparently left out of consideration the yielding walls of the small blood-vessels, and the minuteness of the pores through which absorption occurs. This view of the process of absorption is moreover sufficiently refuted by one of the author's experiments. Thus he remarks that if the communicating tube be introduced into the femoral vein of a dog or horse, and pushed no further, then the inspiration will produce no effect on the fluid in the cup; *because the relative vacuum in the thorax can be filled from the veins nearer to the chest*‡. This latter remark, and the admission that the operation of this partial vacuum

* "L'affinité des parois vasculaires pour les matières absorbées étant supposée la cause, on se l'on veut l'une des causes, de l'absorption," &c. Ibid. p. 8.

† Experimental Researches on the Influence of Atmospheric Pressure upon the Blood in the Veins, upon Absorption, &c. By David Bang, M.D. &c. London, 1836.

‡ Ibid. p. 15.

* Journal de Physiologie, t. i. p. 6.

within the thorax does not extend so far as the femoral veins, appear to be quite fatal to this view of absorption. And even if it could be shewn that the expansion of the thorax exerts a *direct* influence on the passage of blood through the smaller veins, the immense disproportion existing between the area of the latter and that of the minute absorbing pores situated in their walls, would necessarily cause that influence to be exercised chiefly on the fluid contained within the larger tubes. His other experiments, in which the application of cupping-glasses over poisoned wounds prevented the action of the poison, cannot, in their physiological bearings, be considered as proving more than that an obstruction to the circulation through a part prevents absorption—a principle which has also been fully established by many other observers. It is now some time since the idea first occurred to me, that the same power of raising from a lower level, and drawing with it an external stagnant fluid, which Venturi found to be possessed by a rapid stream of water, might possibly also be in some measure exercised by the innumerable streams of blood which incessantly traverse the different structures of the animal body. If any analogous force did reside in the latter, then the total absorbing power thus obtained, must, from the number and rapidity of those currents, as seen under the microscope, be very considerable; and this force had certainly not yet entered into the consideration of physiologists. I repeated, with success, Venturi's chief experiment, viz., that of causing the ascent of a stagnant liquid in the long arm of a syphon, the short arm of which communicated with the interior of a pipe traversed by a rapid stream. And I also found the same ascent to occur, though much more slowly, when a membrane was tied over the orifice of the short arm, so that all communication between the interior of the syphon and the stream could only take place through the minute pores of the intervening membrane.

I had proceeded thus far in the inquiry, when circumstances prevented me from pursuing it further at that moment; but in May last, an abstract of my views on this subject, and of the grounds on which they rested, appeared in the *MEDICAL GAZETTE*.

Having since then performed a great number of experiments on various points connected with this process, I shall now proceed—

1st, to give a detailed account of some experiments, in which the substitution of yielding and compressible, for rigid tubes, (by assimilating the conditions of the observation to those known to exist in the living body), removes the chief, and, in my opinion, the only valid objection to this explanation of the function in question;

And conclude this part of my communication by endeavouring to elucidate the physical principles on which the action of absorption depends.

EXP. I.—A piece of the descending aorta of a horse, which formed a flexible yielding pipe, nearly cylindrical in shape, 4 inches long, and 1 inch in diameter, was fastened horizontally to the lateral opening of the reservoir. Having previously closed all its collateral branches, with the exception of one, I fitted into the latter the short arm of an arched glass tube, the long arm of which dipped into a vessel containing coloured liquid. The internal orifice of the pipe was somewhat contracted in fastening it to the opening in the reservoir, so that its calibre at this point would be less than that of the rest of the pipe. During the passage of the stream through the latter, the coloured liquid rose in the glass tube, and on increasing the height of the impelling column the vessel containing the coloured liquid was speedily emptied. The outer orifice of the glass tube being then allowed to communicate freely with the external air, the jet issuing from the pipe instantly assumed the pulsating character; at the same time that the entrance of air into its interior caused a gurgling sound.

It now only remained to be shewn that a stream traversing a flaccid membranous tube possesses the same power of absorbing an external stagnant fluid. But the difficulties preventing the successful performance of this experiment were much more considerable than any yet encountered; for the mere weight of the incumbent flaccid walls opposed so much resistance to the passage of fluid through the tube, that a copious exudation occurred through any lateral openings existing in it; and I could only obtain a satisfactory result by carefully observing, and in the per-

formance of the experiment strictly adhering to, the conditions under which the return of venous blood is effected in animals.

The most important of these conditions may be thus stated :—

1. The different converging streams always flow from narrow into wider tubes.

2. Those flaccid porous tubes are placed in a dense medium, the pressure of which on their external surface is much greater than that of the atmosphere; for, in addition to this latter force, we have, in the living body, various other powers, the operation of which greatly increases the pressure acting on the exterior of the blood-vessels; as, for instance, the elasticity and contractility of the skin, the weight and lateral pressure of adjacent parts, muscular action, &c.

3. The walls of the terminating portion of the large venous trunks are strengthened and rendered comparatively rigid by their adhesion to the diaphragm, pericardium, and pleuræ.

4. The flow of venous blood into its proper receptacle—the right auricle—is facilitated by the diminished pressure existing within the thorax during the act of inspiration.

It would be tedious to enumerate the different failures which I experienced in constructing an apparatus in which all these conditions should be observed. The following arrangement is that which proved most effectual; and the conditions under which the absorbing stream here acted appear to correspond very closely to those affecting the minute currents contained within the veins.

EXP. II.—The œsophagus of an ox, which formed a convenient membranous reservoir, was suspended vertically, and to its lower extremity was fastened a glass tube, fifteen inches long and one-fourth of an inch in diameter, the lower end of which was re-curved, so that its orifice also looked directly upwards. The extent of tube involved in this curve was not above three inches, the length of the ascending portion being one inch. To the orifice of the latter was then fastened a piece of the small intestine of a fowl, which formed a membranous tube two inches long and about one-third of an inch in diameter; the other end of this flaccid tube was then attached to the short arm of a

glass syphon one-third of an inch in diameter, the arms of which were respectively an inch and a half, and two inches and a half, long (Fig. 2).

Fig. 2.

a. The membranous reservoir; b, the descending portion of the first glass tube; c, its ascending portion; d, the membranous tube; e, the glass syphon; f, the vessel containing the external coloured liquid.

The lower part of the descending, and the whole of the curved portion of the first glass tube, the entire extent of the membranous tube, and the short arm of the syphon, were then placed in a glass vessel six inches deep, on the rim of which the angle of the syphon rested, so that the orifice of the long arm would discharge its contents on the exterior of the vessel (vide Fig. 2).

I must not omit to mention that the lower half of the membranous tube had been previously punctured with a fine needle, so as to make in it a great number of small lateral openings. This was done with the view of rendering the progress of the experiment more perceptible; for the great length of time required for the passage of an appreciable quantity of fluid through the minute pores of several layers of membrane would otherwise have added materially to the tedious character of the observation. It may also be observed, that this enlargement of the

pores facilitated exudation quite as much as absorption; and in the living body the passage of fluids through the coats of the small blood-vessels is greatly promoted by their extreme tenuity, by the high temperature, and possibly by other favourable conditions.

The apparatus being thus arranged, a measured quantity of liquid was poured into the glass vessel, so as to reach nearly to the commencement of the short arm of the syphon, and a column of water, varying from three to five inches in height, was maintained in the membranous reservoir. It will be seen by a glance at the accompanying diagram that the fluid, after entering the first glass tube, and ascending from its curved portion, would then pass through the membranous tube, and reaching the short arm of the syphon, be finally discharged on the exterior of the vessel containing the stagnant fluid.

During its passage through the membranous tube, the stream was, by means of the lateral openings existing in the latter, enabled to communicate with the external stagnant liquid.

The calibre of the arched portion of the first glass tube had been considerably diminished by the flattening of the tube during the process of bending it; so that the stream escaping from it into the membranous tube was necessarily much less than one-fourth of an inch in diameter. But even this disproportion between the area of the stream entering the membranous tube, and that of the latter, did not prevent a rapid exudation from occurring whenever the height of the column in the reservoir exceeded two or three inches; and the following was the only method which I found effectual in obtaining constant absorption, viz. to grasp the upper end of the first glass tube, where it projected into the membranous reservoir, so as gradually to diminish its area until the stream escaping at the other end of the apparatus became reduced in size to a mere thread. And so long as the area of the stream entering the first glass tube was in this manner limited and regulated according to the height of the impelling column, absorption of the external stagnant fluid surrounding the membranous tube proceeded with tolerable rapidity. Thus in one experiment the quantity of stagnant fluid was in less than ten

minutes diminished by three ounces: in another trial, its original quantity of nine fluid ounces was, during the passage of little more than half a pint of water through the apparatus, reduced to $4\frac{1}{2}$ ounces, or one-half. The stagnant fluid was occasionally coloured, and could then be seen to escape with the stream issuing from the syphon. At the commencement of the experiment there was invariably some effusion, until the long arm of the syphon became filled, when the process of absorption began, and, if uninterrupted, would gradually reduce the height of the stagnant fluid from the level of the short arm of the syphon to the junction of the membranous tube with the termination of the first glass tube. When a considerable extent of the membranous tube became in this manner exposed, globules of air also passed through its lateral openings, and escaped with the stream. While absorption was proceeding the membranous tube always became flattened, whereas during the occurrence of effusion it appeared distended, and more cylindrical in shape. In this apparatus the absorbing stream flowed almost directly upwards. In other cases, where the membranous tube was placed horizontally in a long shallow vessel, absorption of the external fluid occurred with the same rapidity so long as the same conditions were observed.

Having, by these experiments, proved that a stream, in passing through a flaccid membranous tube, can exercise an absorbing power, it now remains for me to show that in this rude apparatus there are represented the most important of those conditions which are known to affect the currents of venous blood. And these conditions may be considered in the same order in which they were before mentioned.

1. It is essential to the success of the experiment that the absorbing stream should flow from a narrow to a much wider tube. In this respect there is a marked analogy between the contrivance which repeated failure in these experiments suggested, and that arrangement of the minute veins and the contiguous portion of the capillaries by which the streams of blood traversing this part of the circulating system are made to operate in a precisely similar manner. For at this point innumerable small rapid streams are,

throughout the body; perpetually flowing from the capillaries into the contiguous venous radicles, the calibre of which is much greater than that of the vessels supplying them. At this point, therefore, the conditions are evidently favourable to absorption. And on tracing the course of the veins to their final termination in two or three large trunks, the individual streams are, in the same manner, constantly found to pass from narrow to wider tubes. In the smaller vessels this arrangement is obviously calculated to add to the absorbing power of the contained streams. In the large veins, the walls of which are too thick to be readily permeated by liquids, its chief use is apparently that of economising the impelling force of the vis à tergo, by diminishing friction.

2. The next point to be noticed is the medium in which the membranous tube was placed: and the necessity of a denser medium than atmospheric air was proved by a repeated observation of the fact, that when the membranous tube was unsupported, the whole of the fluid constituting the stream escaped through the lateral openings of the same apparatus which, when immersed in water, not only permitted the stream to traverse it freely, but also enabled the current to carry with it a considerable quantity of the external stagnant fluid. It is difficult to form any estimate of the average amount of pressure acting on the exterior of the blood-vessels of the living body. It must necessarily vary much in different animals, and in different parts of the same body. I have, however, been careful not to employ a greater amount of external pressure in these experiments than might reasonably be supposed to exist in living animals. For in these experiments the force acting on the exterior of the membranous tube never exceeded the weight of a column of water six inches high, while in some cases the height of the external column was only one inch.

3. In imitation of the rigidity of the terminating portion of the large veins, the upper end of the membranous tube was fastened to the short arm of a bent glass tube. But this sudden transition from a flaccid to a perfectly rigid tube occasioned an inconvenience which will, to a certain extent, be avoided in

the animal body, in consequence of the change being more gradual.

4. To compensate for the difficulties which a stream encounters in flowing against gravity, it became necessary to use the slight derivative power of a short syphon, and without this contrivance no absorption could be obtained with an ascending stream. As before mentioned, it has been shewn by the experiments of Hales, and more recently by those of Sir D. Barry, that a similar derivative power acts during the expansion of the thorax. This force has been found capable of raising a column of water in a small glass tube to the height of twenty inches.

It might, from this latter circumstance, be imagined that the use of a more powerful syphon in the apparatus would have the effect of increasing the activity of the absorbing process. But I have satisfied myself, by repeated trials, that any material deviation from the above-stated proportions, whether increasing or diminishing the power of the syphon, rather impeded than promoted absorption. For when the derivative power was much increased, the gravitating column of water in the long arm diminished the pressure within the short arm so much, that the contiguous portion of the membranous tube was then forced against the orifice of the latter, so as entirely to close it. And this obstruction to the passage of the stream necessarily caused effusion through the lateral apertures of the membrane.

This inconvenience attending the employment of a more powerful syphon, would, I conceive, be experienced in a minor degree were the change from a flaccid to a rigid tube more gradually effected, as it is in the animal body. And to test the accuracy of this supposition, I repeated some of the former experiments with a more powerful syphon, having previously fastened to its short arm a piece of caoutchouc tubing half an inch long, and over that a membranous tube six inches in length. Although every other condition was the same as before, this slight alteration of the apparatus, by which the stream was made to pass from the membranous into the caoutchouc tube, and then into the glass syphon, facilitated the action of the latter so much, that a very rapid absorption of the ex-

ternal fluid occurred, though the lateral apertures in the membranous tube did not approach within three inches of the termination of the cacutchouc tube.

In explanation of this point, it may also be remarked, that though the derivative power exercised by the act of inspiration arises from the same immediate cause as that by which a syphon acts, viz. diminished pressure within the several recipient cavities, the mode of action of that cause nevertheless differs somewhat in the two instances. For when the long arm of a syphon is once filled, the gravitating column of liquid within it instantly acts with its full power in inducing a tendency to the formation of a vacuum in the portion of tube immediately behind it; whereas, the act of inspiration being a gradual effort, the enlargement of the thorax occupies a perceptible interval of time. And therefore, though the partial vacuum formed within the latter may ultimately be capable of raising a column of water to the height of twenty inches, it by no means follows that the derivative force acting on the contents of the large venous trunks is, *at any one moment*, equal to that of a gravitating column of water of this height. On the contrary, as this imperfect vacuum is continually being removed by the influx of fresh blood into the thorax, it appears tolerably evident that during an ordinary inspiration this derivative force does not at any one time exceed that of a falling column of water of the same area as the large veins, and three or four inches in height. And if the truth of this remark be admitted, there will then be a tolerably close approximation between the derivative force acting in the living body and that exercised by the syphon in these experiments.

As proving that the absorption and discharge of the stagnant fluid did not depend upon the *direct* action of the syphon, I may mention that the syphon acted so long only as the stream continued to flow through the apparatus. For when that flow ceased the membranous tube was pressed against the orifice of the short arm of the syphon so as to close it; and the long arm then speedily became emptied.

In addition to those already mentioned, there is one other condition

which, in the animal body, is found to be essential to the proper circulation of the blood, and more particularly to the due performance of the function of absorption: for it has been clearly proved by the experiments of Hales, and by the experience of all practical anatomists, that in general none other than a thick or viscid fluid can pass through the minute blood-vessels without the occurrence of a very copious effusion. And the truth of this observation is also strikingly exemplified in certain phenomena of disease. As to the manner in which this physical property of the blood assists absorption, it does not appear to me that it exercises any other than an indirect action, viz., that of rendering the blood less apt to escape through the pores of its containing vessels: for as a certain amount of lateral pressure is required to overcome the cohesive force of the particles of blood, and as the impeding causes which occasion that lateral pressure are, in the veins, very few in number, and trivial in their character, it is probable that, in a state of perfect health, little or no effusion takes place through the walls of this portion of the circulating system. To render the chain of evidence more complete, I repeated the same experiments with membranous tubes, observing every particular as before, with the single exception of substituting a viscid fluid, viz. common size, for water; and absorption went on quite as well as when the more mobile liquid was used; there being, moreover, this additional advantage, that the progress of the experiment was less liable to be disturbed by effusion during any slight disorder of the apparatus.

The whole of these considerations will, I trust, be deemed sufficient to establish the principle, *that a stream, while traversing a flaccid membranous tube, can, under certain favourable conditions, exercise an absorbing power*; and if the correctness of this statement be admitted, it will not be difficult to reconcile these views with the knowledge already possessed on the subject of the process of absorption in animals; for as it is fully proved that the act of circulation, or, in other words, the passage of the blood through the minute vessels of the part, is essential to the occurrence of absorption, it now only

remains to inquire, 1st, what particular part of the circulating system is the more especial seat of this function, and 2dly, in what manner the passage of external fluids into the blood-vessels is accomplished.

[To be continued.]

CASE OF ENCEPHALOCELE,

OR

HERNIA CEREBRI.

By W. LYON, Esq.

Lecturer on Surgery, and lately one of the Surgeons of the Glasgow Royal Infirmary.

(For the Medical Gazette.)

IN the Edinburgh Journal of Medical Science for May 1842, I detailed, and added some observations on, a case of hydrancephalocele, which protruded on the face. I recently met with another instance, nearly similar to this rather rare morbid condition, where the tumor, which was of large size, existed over the occiput; and as it possessed some unusual features I herewith annex an account of it, in the hope that it may prove useful to the surgeon, anatomist, physiologist, and obstetrical practitioner, with each of whose departments it would not be difficult to shew that it had some connection.

March 1st, 1844.—Child of — W., a male, was born this morning, having been ushered into the world under the auspices of a midwife, who reports the labour to have been very easy and rapid.

Situated over the occiput, and nearly of the bulk of the head, being of the size of a large fist, there is an oblong tumor, the upper part of which is level with the crown of the head, the lower margin resting on the nape of the neck, or almost descending between the shoulders when the head is thrown back. It measures 11 inches in its largest circumference, 9 where attached to scalp, 7 from side to side, and 8 over the surface from the superior to the inferior attachment. It feels tense, is livid at some parts, and opaque, but softish and obscurely fluctuating, and does not pulsate. The anterior half of the tumor has thin soft hairs scattered over it where not livid, and its surface has a marbled appearance, and is traversed by numerous small tortuous vessels. No abnormal opening can be

felt under the attachment of the tumor. The head is of ordinary size, but the forehead is remarkably low and receding, and the facial line much more oblique than usual. The child is of average size, and otherwise well formed; it is weakly, does not suck freely or actively, and cannot be made to cry, although it readily winces when pinched or pricked. The midwife strenuously insisted on the tumor being opened, and said she would have opened it herself before my visit if the parents had not objected.

The forehead was low and receding; but the cranium being nearly of normal size made it unlikely that the tumor, about as large as the head, was solely occupied by protruded brain: and the absence of brain was rendered still more probable from pulsation, commonly in such conditions present, not being felt.

There was extensive ecchymosis on the surface of the tumor, in all likelihood in consequence of pressure during its passage through the pelvis: had it not been for the prominence and well-defined form of the tumor, the ecchymosis might have led to the supposition of its being one of those tumors formed during labour by extravasation of blood between one or other of the layers of the scalp.

From not possessing pulsation or transparency, from the fontanelles not being prominent, nor capable of being made so by pressure on the tumor, the connection of its contents with the interior of the cranium or brain was rendered doubtful. The child not being able to cry prevented that assistance in the diagnosis which is obtained from observing whether the tumor becomes distended and tense under the effort of crying—one of the phenomena usually present in cases of congenital protrusions from the cranium. But the want of transparency could be accounted for, like the ecchymosis on its

surface, by pressure during its transit through the pelvis causing extravasation of blood into its interior; and, all things considered, Dr. James Watson, Dr. John Macfarlane, and I, concluded that it had a communication with the brain, and therefore dissuaded the parents from any active interference. Gentle compression, by an elastic cap, was tried; but it was difficult to keep the cap adjusted so as to be effective, and it was therefore soon abandoned. Our conclusion in regard to the probable communication between the tumor and the interior of the cranium was rendered positive in a few days; for the tumor becoming flaccid, by pushing the finger upwards from the middle of the inferior attachment, the edge of an opening into the cranium could be nearly unequivocally felt.

The child soon refused to suck, daily lost flesh and strength, lay constantly in a partially comatose state for eight or ten days, could with difficulty be made to swallow, and died on April 1st, exactly one month after its birth.

Examination of the head.—The parietes of the tumor were formed by the scalp, pericranium, and dura mater; the cyst contained about three ounces of sanguinolent serum. Portions of the posterior lobes of the cerebrum, about the bulk of a small apple, covered by the arachnoid and pia mater, and having a film of serum intervening between them and the dura mater, projected into the cyst, through an opening the size of the point of the finger, at the inferior and middle part of the occipital bone.

This opening had rounded edges, and was situated immediately above the tentorium, which was incomplete. The opening was bounded above by the termination of the longitudinal sinus, at the sides by the lateral sinuses, and below by the imperfect tentorium.

The portion of brain which projected into the tumor was compressed where it passed through the opening, and bulged out to the size of a small apple in the interior of the cyst. There was no fluid below the membranes within the cranium, nor in the ventricles. The brain was of healthy consistence and colour. The body was not allowed to be examined.

The appearances on dissection explained why the signs of hydrencephalocele were not present in this instance;

and it may be of some practical importance to be aware that a diseased state nearly similar may exist, while the signs usually considered to characterize hydrencephalocele, or hernia cerebri, are absent.

The portion of cerebrum contained in the cyst accounted for the small receding forehead.

I have already explained why the tumor did not possess transparency. The absence of pulsation, and incapability of causing prominence of the fontanelles by pressing the tumor, are easily accounted for by the opening between the interior of the cranium and the cyst being so impacted with brain as to prevent free passage of the serum, or free circulation in the vessels of the protruded portion of cerebrum. The weakness of the child, its inability to suck or to cry, and the comatose state in which it lay, in all probability arose from the partial strangulation which the portion of brain suffered from the edges of the opening through which it passed.

Strictly speaking, therefore, this should be called a congenital hernia of the brain: allowing for difference of parts, the conditions were exactly like those in protrusions from the abdomen, and were probably produced in a similar manner. There was the opening, abnormal here, the protrusion, the sero-sanguinolent fluid, and the sac: from interrupted osseous development there had been diminished resistance at a part of the occipital bone; or there may have been hypertrophy of brain. From one or other of these causes, the cerebrum, covered by its membranes, protruded; pressure on the protruded membranes by the edges of the opening occasioned transudation, separation of the dura mater, and thus formation of the sac.

The case affords an additional proof of the vagueness of the diagnosis in cases of this kind, explains some of the causes of the varying characters which cases of this disease present, and its detail may, I hope, prove useful to the profession.

There is an account of a case closely resembling the above in Collins's *Practical Treatise on Midwifery*, page 511. The tumor was nearly as large as the head; it burst two hours after birth, and the child died eight hours afterwards. The ventricles in this case

communicated with the sac; the opening in the occiput was three-eighths of an inch in diameter, and was situated half an inch behind the foramen magnum.

In the MEDICAL GAZETTE for the 5th of April last, there is a description of a "bicephalous monstrosity," which I have a strong conviction was a case closely resembling, if not identical with, the one I have above detailed, and which affords an additional example, if I am not mistaken, to the many where errors in diagnosis have been committed with reference to congenital tumors situated on the head. The account is altogether a vague one: the description of a "large mass, rather larger than the head," near the posterior fontanelle, being a "false head," and having a mere "cleft for the eye," "an elevation in the seat of the nose," and "a fold in the place of the mouth," while there were no bones of the face, no eyeball, no "cranium," lead me to think that the writer has been more influenced by his imagination than led by his judgment in his description.

Having arrived, however, at the conclusion that the child was bicephalous, Dr. Buering, the narrator of the case, determined to cut off one of the heads of his patient.

So far as I am aware, decapitation is a new surgical operation; though it is the belief of some that it is scarcely a more serious one than certain procedures occasionally adopted.

It is not stated whether he had any difficulty in deciding which of the heads he would remove; but probably, influenced by the less handsome appearance, and the inconvenient position of the posterior one, he first laid it open, and then passed a ligature around the pedicle which attached it to the other.

It is not unusual, we believe, for death to occur from the loss of a head; and Dr. Buering's patient was no exception to the general rule, for on making his visit the following day, the parents informed him, with "great satisfaction," that his patient was dead; and, I think they might have added, that the Doctor's procedure had had some considerable part in killing it.

The whole details forcibly impress me with the belief that Dr. Buering's case was one of congenital encephalocle, or hernia cerebri. When he tightened his ligature, "the respiration

became quickened and forcible, the pulse frequent, hard, and small, the pupils dilated, and the blood-vessels of the head and face injected, so much so, that the jugular vein became apparent "through the thick layer of fat which covered it." These symptoms caused him to take blood from the jugular; and upon giving a "third pull" to the ligature, a stream of blood "burst forth" from the orifice in the vein.

All these conditions are easily explicable on the supposition that his ligature acted on the longitudinal and lateral sinuses, and on the portion of brain protruded from the cavity of the cranium, and contained in the pedicle of the tumor; while they cannot be explained if his description be correct, that "there was no cerebral connection between the pseudo-cephale and the normal head."

My convictions respecting the case are strengthened by the farther description given by the author. On looking into the interior of the tumor, he found a "regular dura mater,"—"a falciform process"—"an imperfect tentorium;" &c. Had I laid open the tumor in my case as he did in his, the hernial protrusion would have presented with "two normally-formed hemispheres," "parted by a deep sulcus," &c. &c. exactly as in his case.

He subsequently states, that the "encephalon of the normal head was perfect in all its parts." With the ligature surrounding the protruded part of the dura mater, the loss of the cut-off portion of cerebrum would not be very conspicuous; and considering the error in diagnosis I suppose to have been committed, and the consequent operation, I am uncharitable enough to withhold my faith in the correctness of the description of the pathological appearances; and to conclude from the whole incongruous account given in the extract from Caspar's Wochenschrift, in the MED. GAZETTE, that the details have been drawn up less with reference to the actual appearances than in unison with preconceived notions; that Dr. Buering has added another mistake to the many committed in respect to the diagnosis of congenital tumors on the head; that he cut off by his ligature a part of the cerebral lobes projecting into the tumor; that from a hasty examination he did not observe any imperfection in what

he calls the "normal encephalon;" or that there is a direct though unintentional misrepresentation, occasioned by the desire of the narrator to bring his erroneous impressions in support of the reasoning on which he determined and practised his unfortunate interference; which, even on his own showing, was replete with danger, and totally uncalled for.

CASE OF PARAPLEGIA TREATED WITH STRYCHNINE.

To the Editor of the Medical Gazette.

SIR,

THE manifest efficiency of strychnia in a case of paraplegia which has lately occurred in my practice, induces me to offer it for insertion in your journal.

Miss Rixon, aged 13, had been attacked between five and six months before I visited her with pneumonia, attended by its usual symptoms, and for which she had been subjected to the ordinary treatment. About a month after the attack she lost the power of moving her lower limbs, and her voice was reduced to a whisper: her appetite then began to fail, and the action of the bowels became so torpid as to require the use of frequent purgatives. General emaciation followed; the limbs wasted and became cold, and so entirely void of all sensation as to be insensible to any stimulus which was applied. She was unable to bend either knee, but especially the left, without assistance; and the paralysis was so complete as to render her perfectly unable to use or even to move the legs. She complained also of pain in the head, and want of sleep. To remove these symptoms she had been put into hot baths, the limbs well rubbed, a blister had been placed down the spine, and she had been put on a course of tonic combined with purgative medicine, by the medical practitioner who attended her. But even these judicious measures had failed to produce any material benefit, and her friends had given up all hope of her ever recovering the use of her feet.

On my first visiting her, on March 22d, and finding her in this distressing condition, I ordered her another blister on the nape of the neck, which was kept open by the Unguent. Sabinæ for

several days, and prescribed the following purgative:—

℞ Hydrarg. Chlorid. gr. $\frac{1}{2}$; Ext. Colocynth. comp. gr. ij.; Ext. Nucis Vomicae, gr. $\frac{1}{2}$. Misce, fiat pilula 6tâ quâque horâ sumendâ.

On March 25th, finding the bowels not sufficiently relieved, I increased the Ext. Col. comp. to gr. iij., and the Ext. Nucis Vomicae to gr. $\frac{1}{2}$ in each pill, and directed them to be taken as before.

31st.—The symptoms much the same. The blistered surface so ulcerated and sore as to cause great uneasiness, and disturb her rest.

Omitte Unguent. Sabinæ.

℞ Unguenti Plumbi Acetat. 3iv.; Unguenti Zinci, 3ij.; Pulv. Opil, gr. v. Probe simul terantur, et applicetur bis quotidie parti exulceratæ.

Perstet in usu pil. 6tis horis.

April 5th.—No use or sensation in the limbs; great debility; tongue red; pulse 110; no appetite; blistered surface soothed, and healing.

℞ Mist. Ferri comp. 3j.; Decoct. Aloe comp. 3ss. M. ft. haustus bis quotidie bibendus.

℞ Hydrarg. Chlorid. gr. j.; Ext. Coloc. comp. gr. ij.; Ext. Hyosc. gr. iss.; Ext. Nucis Vomicae, gr. $\frac{1}{2}$. M. ft. pilula singulis noctibus sumenda.

22d.—The voice stronger; bowels still constipated; pulse improved; no appetite; feet quite cold and powerless, and entirely insensible to the touch, or even to pinching.

℞ Strychniæ, gr. j.; Cons. Rosæ, q. s. ut fiant pil. xij. è quibus sumat unam bis quotidie.

℞ Hydrarg. Chlorid. gr. j.; Ext. Coloc. comp. gr. v. M. ft. pil. horâ somni singulis noctibus sumenda.

May 2d.—Symptoms as before.

Augeatur Strychnia ad gr. $\frac{1}{2}$ in quâque pilulâ.

16th.—Has more warmth in her feet than she has experienced for some time, and says that she feels "a pricking and jumping sensation in them, and down the spine and lower extremities." Two days ago she had pain, and a slight swelling of the great toe; and yesterday she felt very restless, irritable, and "queer," and the pricking sensation increased. Bowels still torpid.

℞ Strychniæ, gr. $\frac{1}{2}$; Pil. Aloe comp.

gr. iij. M. stat pil. ter quotidie sumenda.

20th.—I this morning received the following note from her uncle:—

"Sir,—I have the pleasure to inform you that Miss Rixon has recovered the use of her feet, and actually walked down stairs this morning, &c.—I am, sir, your obedient servant, W. WELLS."

21st.—On visiting her to-day, I had the gratification of finding this note verified by her walking across the room to meet me as I entered. She had experienced no unpleasant effect from the pills, and had entirely recovered the warmth and use of her feet and legs. She could also talk aloud as well as ever she could. I desired her to continue the strychnia pills twice a day for a short time; and she is now gone to Brighton for the restoration of her strength, which I find, by a letter which I lately received, is gradually returning, and she is able to walk out daily without support, and without any inconvenience.

I wish it to be distinctly understood, that in offering this case to the attention of your readers, I am not laying claim to any discovery, or to any particular novelty in practice. The efficacy of strychnia in those cases of "paralysis which seem to arise from diminished nervous excitement" has been already detailed by Dr. Bardsley and others; and as I could not detect, on examination, any organic cause for the paraplegia, I anticipated the probability of a favourable result. My principal object is to corroborate the recommendation of this remedy where the ordinary treatment has proved abortive. I have at this time two cases of paralysis under my care, in whom it also promises to afford relief; and although strychnia is a most deleterious medicine when improperly administered, it is a very valuable one in the hands of a careful and observant practitioner. Indeed, in cases where larger doses than I have prescribed have caused rather alarming consequences, the immediate discontinuance, and a liberal supply of stimulants, have very quickly removed them, and enabled the patient to resume the medicine.

I am, sir,

Your obedient servant,
J. C. BADELEY, M.D.

Chelmsford, July 2, 1844.

867.—XXXIV.

THE CONSTITUTION

OF

THE MEDICAL PROFESSION AT HOME AND ABROAD.

By SIR GEO. LEFEBVRE, M.D.

THE subject of medical reform, which amounts at present to a species of agitation, seems to me to embrace two important questions; the one, whether every practitioner in medicine should be considered qualified by education, and consequently called upon by the public, to exercise every branch of the healing art; or whether the community will be best served by a subdivision of labour, which, in all matters connected with the arts and sciences, has been attended with the most useful results. A long residence in foreign countries has had its weight in influencing my opinions, and compelled me to believe that, under proper regulations as regards education, and with such gradual reforms as time will necessarily produce, the profession, as it is practised in this country, does not require any great legislative interference, and that, abating some abuses, which are the inheritance of all human institutions, the public is nowhere better served than by the three classes of practitioners who are at present recognized by the laws and common consent of the country.

It is to be borne in mind that, between legislative enactments and practical applications, a wide chasm intervenes; and we find, in most circumstances of life, that the evasion of laws is much easier than their enactment. In nothing does this hold good more than in the medical profession; and in spite of all the reform-bills which consummate wisdom may produce, the public will consult its own interest, or at least what it believes to be such, and there will be always a sufficient number of practitioners actuated by the same principles to indulge it in its caprices.

Upon a *prima facie* view of the subject it does appear that a man is more useful as he is enabled to render every assistance that his art professes to do; but this omnipotence is not the lot of every man. Nature has endowed us with different talents; and if we have them not by birth, it is practice

None that can make up the deficiency. Now this practice is, in many instances, not to be afforded us under all circumstances; but as it is afforded to many who possess local advantages which others do not; so here is at once a separation in the branches of the profession. A man residing in a country town may possess every educational requisite for performing the operation of lithotomy; but the first patient who presents himself with that disease will say, "whatever confidence I may have in my ordinary attendant, I know that he has not performed that operation, and I shall be safer in the hands of a man who has done it frequently." He will remove himself to London, or some metropolitan town, and put himself under the care of, not any of its surgeons indiscriminately, but of the one who has the greatest reputation in this line. If he be a poor man, and has not the means of so doing, he will find means of being transferred to a county hospital, where he will receive all the advantages of the more opulent sufferer. The general practitioner will have to rest upon his oars, and may pursue a long and useful career without ever having an opportunity of doing that which, did it occur, he would most probably do with great credit to himself; and we do boldly and fearlessly assert that a more useful, deserving, and, in the present day, a better educated class of men, are not to be found in any country than such as now exists in England.

Acting upon the principle that practice makes perfect, the public will resort to those whom they consider best qualified for treating any peculiar disease; and this will necessarily split the profession into branches, which no legislative interference will be able to tie indissolubly together.

As life is not long enough to make us equally well acquainted with every branch of our art, we shall be compelled, by public opinion and patronage, to devote ourselves to some one in particular, and in doing so we shall best serve our own interests and the public good. As regards surgical operations, practice alone will never suffice, if we have not manual dexterity conferred upon us; and no advantages thrown in our way, no public institution over which we may preside, will mislead those who apply for our assis-

tance. The separation of the two branches of physic and surgery is not, what some wish to have it understood, a nominal division; it is founded upon natural laws, and formed from natural consequences. Medicine and surgery, to use the words of the late Mr. Abernethy, are not what the French republic professed itself to be—one and indivisible. They may be so in theory; they should be so. Every practitioner should be acquainted with all the features which diseases of all kinds present to observation; for how is a surgeon to treat a local disease if not acquainted with the constitutional symptoms to which it may give rise, and the physician may work in the dark if ignorant of the same causes; but pathology and manual dexterity are not synonymous, they are not co-equal powers; and as such the public will never appreciate them.

In a metropolis like London, and in the higher lines of practice, this distribution of labour is, and ever will be, attended with advantage to all parties, and it would be still more so if the two branches did never trespass on each other's callings. No man of eminence finds that life is too long to be devoted to either branch, and we may not be wrong in asserting that those who have made peculiar diseases their whole study are not the least useful members of the profession. Whence arise the manifold improvements in modern times but from devotedness to specific objects—such improvements bearing the names of those who discovered them; and, abounding as the means of alleviation have done within the last twenty years, it is a libel to say that our art does not keep pace with the other arts and sciences. We may instance the operation for crushing the stone, the merciful invention of the water-bed, the cure of organic deformity in the expression of the eye, and a host of minor contrivances to palliate human suffering. These have been, for the most part, the work of individuals who have devoted their attention to special objects.

So much for the advantages of maintaining the present system as regards this grand division of labour, which is recognised as it exists between medicine and surgery. It is now worthy of examination whether any advantage is to be gained by annihilation of the general practitioner, who can have no

fears himself upon the subject, feeling persuaded, as he must be, that a member of society so eminently useful as himself will always meet with sufficient patronage. Any measure which attempts to render him less respectable than his present education guarantees him to be, any plan of swamping him by allowing those of inferior education, or, what is the same thing, of inferior means of education, to trample upon his rights by claiming equality with him, is a thing as monstrous in conception as it is criminal in effect. The object of the legislature, if it have any in its proposed reform, should be directed to facilitate education, but to insist upon its perfectability; not to throw a less informed class upon the public, but to secure to it effective assistance by more stringent laws for those who may hereafter be called upon to exercise their art; to raise them to the consideration enjoyed by the higher class, not to reduce them to the level of the leech. The qualifications of quondam general practitioners are equal at present to what the physicians of former days could boast; and who but the public has gained by their elevation? It must be remembered that nine-tenths of the public are in their hands, and that they are responsible agents.

It is impossible to dispense with this class, and it is the duty of the legislature to make them worthy of their calling. To whom are they more requisite than to the physician or surgeon in their attention to the general details of cases, to which the former, in very extensive practice, could not duly attend? and where they act in concert, honourably and conscientiously, all parties are benefited by this distribution of labour.

No man can stand alone in his profession; society is a chain of which every link is equally essential to its integrity; and it is upon the division of the *strains* made upon it amongst all its pieces that the whole preserves its state. In the country, and in smaller towns, the general practitioner is the man upon whom all responsibility devolves; and if he be a man of education and information, he maintains a high rank in society.

The mode of remuneration of general practitioners is a continual subject of discussion, and demands cool and deliberate attention. It is asserted by those who would wish to introduce

reform, that it is derogatory to the medical man to receive remuneration for his time and talents by charging it upon his drugs, and that as he has no other means of payment, so the temptation may lead to great abuses. Those who view it in this light, therefore, would introduce the clause that *no man who prescribes should be allowed to dispense, and that no dispenser of drugs should be permitted to prescribe them*. This proposition we ourselves advanced many years ago, in a pamphlet upon Medical Reform; and we are obliged to confess that we must retract our opinions upon that point.

In the first place, as regards the stigma which some attach to it, we do not conceive that what has been long established by custom as most useful and beneficial to the public, can deserve the term derogatory, arguing necessarily from the use, and not the abuse of the principle; for we shall find that abuses equally prevail where this system is not adopted. To the pure all things are pure, and it is a very great convenience to the generality of people to be supplied with the prescription and the remedy from the same source; as far as regards the lower orders in this country, it is altogether indispensable, for hardly is it possible for them to pay the lowest price for their medicines, and what chance would they have of any attendance if obliged to pay a fee, however small it might be, and then pay again for its value in kind? As it is, the poorer class, by which it is not understood mere paupers, do obtain a certain credit with the apothecary, who never refuses his aid in cases of distress, and supplies what is necessary; but the mere dealer of drugs would give no credit, and the patient would be deprived often of such assistance as, when timely administered, will prevent serious illness, the effects of which might bring him to destitution.

It would be necessary for the government to adopt a system which prevails in Russia, where the druggists are obliged to furnish all those who apply *in formâ pauperis* with medicines gratis, or at the prime cost, for which they receive some equivalent from the state.

In reply to the assertion, that the mode of remuneration presents the temptation for great abuse, by forcing more medicines upon the patient than is necessary, we have to reply, that no

legislative enactments will be sufficient to prevent such, and that no greater abuses occur than in those countries where the general practitioner does not exist.

We believe that great changes have taken place in England in this respect; that as the apothecary has become obsolete, and as the remunerating public has been made aware of the difficulties under which the general practitioner is placed upon the score of remuneration, a certain understanding exists between them: a modicum of medicine, and a larger fee for attendance, is more congenial to both parties. That a superabundance of medicines has been dispensed, and may be at present in some cases, cannot be denied; and this, perhaps, is the greatest premium to the system of homœopathy and other species of quackery; but this is the abuse and not the legitimate use of such means; and where the will is the same, similar means will be found of carrying it into effect under any new system which may be adopted.

The man of low education, the mere tradesman in medicine, who now finds it his interest to deal dishonestly with his patient in this wise, would continue to do so although he might be obliged to shift his ground. He and the vender will be in collusion, and the patient will have nothing less to pay for his drugs, and something more to pay for the sign manual which warrants their issue from the laboratory. We have seen this abuse carried to an incredible pitch in foreign countries, where the druggist has a deduction of forty per cent exacted upon his charge; so that medicines are as dear when purchased from wholesale dealers as from the dispensing practitioner. In many instances the physician has no other means of remuneration; for the patient is unable to pay him his fee, which he gets in the per centage from the druggist, who will not make up the prescription but for ready money; so that the patient in narrow circumstances is much worse off than when he has to pay but one fee for advice and medicine. We have been long eye witnesses to the evils produced by such collusion, which makes us averse to any change in this respect. We do not impugn the respectable members of the profession; but disreputable men are to be found in all professions, and in all countries of the earth; and such will

always find means of acting dishonestly in spite of all legislative enactments. This is of itself a most urgent and undeniable reason for not throwing the profession open to men of inferior rank and education, for the injury to society will be irreparable by such a proceeding. This involves the question of medical education, which we propose to speak of hereafter.

A question also of considerable importance to the profession remains to be discussed, in regard to the fees to which practitioners will be entitled. If the different classes are to be awarded different fees, it will be more invidious, and productive of more jealousy and ill feeling than at present exists among its members. The general practitioner is satisfied with his present system of remuneration, and it is such as best suits the public in general; but if he is at once to rise to the higher rank, and the latter to descend to his, there must be an equality also in pecuniary compensation;—and how are the junior members of the profession to hope for the same patronage which is the reward of high talent and experience? It is by degrees only that the junior works his way up the professional ladder, and he feels safe when he has gained the summit. His footing is then sure; whereas to place him there at once would be to threaten his downfall. We feel convinced that no great reform is necessary other than every effort to amend abuses; and that the present division of labour, where the classes as they now exist act in honourable, harmonious concert with each other, is calculated to supply all the medical wants of the British public, and is the most worthy of its patronage.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Anatomico-Chirurgical Observations on Dislocations of the Astragalus. By THOMAS TURNER, Surgeon to the Manchester Royal Infirmary, Lecturer on Anatomy, &c. &c. Pp. 138. 8vo. 1843.

THESE observations were originally published in the Transactions of the Provincial Medical and Surgical Association, and are now presented to the profession as a separate work. This volume

contains an account of forty-five cases of dislocation of the astragalus, of which twenty-four were simple, and twenty-one compound.

<i>Of the Simple Cases.</i>		
Partial	3	{ Without fracture 2
		{ With fracture 1
Complete	21	{ Without fracture 13
		{ With fracture 8
<i>Of the Compound Cases.</i>		
Partial	2	Both without fracture.
Complete	19	{ Without fracture 13
		{ With fracture 5
		{ With dislocation of the ankle 1

Mr. Turner lays down the treatment applicable to these varieties of dislocation, particularly insisting on the expediency and safety of excision of the astragalus in complete, compound, and isolated dislocation of the bone.

If the astragalus be partially dislocated, and not twisted round, as it often is when the dislocation is complete, there is reason to hope that reduction may be accomplished. In simple, direct, and complete luxation, when attempts at reduction have failed, Mr. T. recommends that the bone be allowed to remain in its new situation until the skin begin to ulcerate; he then makes an incision over the bone to relieve tension and pressure; when the bone is detached from the circumjacent textures by the natural process of separation, he removes it. In simple, indirect, and complete luxation, it may be anticipated as a matter of certainty that the bone will die and require dislodgment. To take off tension and pressure from the angles of the displaced bone, Mr. T. advises that an incision be at once made over it; but he does not then remove the bone, lest the exposure of the cavity of the joint may have an injurious effect. In complete compound luxation, he advises the immediate removal of the astragalus; and a careful perusal of the cases

which Mr. Turner has brought forward confirms our opinion of the soundness of the practice on which he so forcibly insists. It is certainly a much more judicious proceeding to excise the luxated bone, than to attempt by long-continued and violent means to reduce the dislocation.

Respecting the operation, Mr. T. says, p. 113, "it may be very easy, and free from danger, when the bone has been almost wholly separated from its connecting ligaments and other textures; but in other cases the attachments may be so firm, and the space in which we have to dissect so much encroached upon by displaced tendons, and the posterior tibial artery so denuded of its protecting covering, as to render the operation of extirpating the bone not only exceedingly difficult, but, without great care, exceedingly dangerous. This latter circumstance, however, is the main source of danger, as the artery is much exposed; and in some instances it has ulcerated or sloughed, and given issue to alarming hæmorrhage."

The following is a table of the treatment, and of the result, in each of the cases which Mr. Turner has given; one of them being twice particularised here, owing to its being an example of partial excision as well as of partial reduction:—

No.	Treatment.	Result.
2.	Partial reduction	{ Permanent inflexibility 1
		{ Tolerable motion 1
6.	Complete reduction	{ All did well, with tolerable, and some with perfect motion.
10.	Bone allowed to remain in its new locality.	{ Anchylosis 1
		{ Deformity and impaired motion 2
		{ Imperfect motion 1
		{ Result not published 1
		{ Useful foot (all backwards) 5
6.	Partial excision	{ Deformity and permanent lameness 1
		{ Deformity, with a tolerable foot 1
		{ Anchylosis 1
		{ Useful foot 3

18. Complete excision	{ Anchylosis	1
	{ Useful foot	13
	{ Death	4
4. Amputation.	{ Recovery	3
	{ Not recorded	1

*Of the 18 cases of complete excision,
In 10 the operation was immediate.*

1 on the second day.	{	Simple cases	3
1 on the eleventh day.		Simple and complicated	3
1 after four weeks.		Compound cases	10
1 after thirty-three days.		Compound and complicated	2
1 after ten weeks.			
2 after fourteen weeks.			
1 after seven months.			

It is worthy of remark that the dislocation was *backwards* in all those cases where a useful foot was the result, where the bone was allowed to remain in its new locality.

Mr. Turner's work does not include all the cases of dislocation of the

astragalus which are on record, nor are the authorities to which he refers mentioned with sufficient precision; still the work is a valuable one, and ought to be carefully perused by every practical surgeon.

MEDICAL GAZETTE.

Friday, July 12, 1844.

*"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."*

CICERO.

BOARDS OF GUARDIANS, THE HORSE GUARDS, AND THE AD- MIRALTY, *versus* THE MEDICAL PROFESSION.

INDIVIDUALS, if sometimes ungrateful to us for our services, are very often otherwise, and besides shewing themselves anxious for our friendship and good opinion, behave to us munificently,—(us and our, refer of course to medical practitioners). Public bodies seem invariably to behave ill to the members of the medical profession. It is well known that Boards of Guardians deal with us precisely as they deal with the contractors for soap, candles, beef, and bread. Their rule of selection in reference to such necessities is quality combined with price. Every man holds himself, and indeed is, a judge in this direction.—A dipped candle is of a good or a bad colour; it burns well, or it burns ill, &c.: in this, and in parallel cases, there

can be no mistake. But when the test of price comes to be applied to a tender for medical service, it is quite another affair: here a Board or Committee have no means of judging whether the thing proffered is dear or cheap. The lowest-priced article, indeed, is generally the dearest, as it is almost necessarily the worst.

Men collectively far higher than the individuals who generally compose Boards of Guardians, however, very commonly show not only an indisposition to exalt, but a positive inclination to depress the medical profession. It is the individual perseverance and resolution of the present Director-General of the Army Medical Department alone that has placed the army medical officer in the position, such as it is, which he holds. Till within a very few years the naval medical officer actually held no commission; he was a mere warrant officer, and took rank with the boatswain, gunner, master, and carpenter. It is to the long approved intercession with the Admiralty of the present Physician-General to the Navy, Sir William Burnett, that we are at length freed from this slur upon the respectability of our position when afloat.

It is well known that many of our regimental surgeons distinguished themselves greatly during the Peninsular war by dressing the men on the field, in front of the enemy. At the Horse Guards, however, there has still been an obvious unwillingness to allow the modern Podalirii and Machaons their reputation for courage acquired in this way; and courage it evidently was of the highest kind,—not that of excitement, and when the blood is up, but that of the consciousness of doing a humane and necessary duty. The medical officer's place has, on various occasions, when the feats referred to have been quoted by way of doing him honour, been declared to be the rear, though no one ever ventured to assert his title to that position: "How should I have been regarded," said our friend, Dr. ———, to us one day, speaking of this matter, "had I said 'my place is in the rear,' when an orderly came for me to look after our Colonel, who had been knocked down thirty yards in advance of the regiment? My instructions were 'the rear,' indeed, but I went and saw to the Colonel's hurt, and had him carried off amidst a perfect hail-storm of shot." "The Duke" is said not to like the medical profession; he was never seriously hurt himself. Yet he has always been very true to some of his old campaigning medical friends, and we have heard that he was rather partial to Sir Astley Cooper, who used to call him the *Dook*.

The indisposition to estimate the medical profession at its true price, its cultivators at their real value, alluded to above, is plainly seen on all occasions, both at the Horse Guards and the Admiralty. In the army we have Sir James M'Grigor as our representative, and a man truer or stauncher to the interests of the department he represents never lived. If every thing we have a claim to as army medical officers be not ac-

corded us, we are perfectly certain that it is because Sir James M'Grigor, with the exercise of his utmost influence, has not been able to have it otherwise. All the world is acquainted with those admirable reports on the sickness, invaliding, and mortality among the British troops stationed in the several quarters of the globe. The value of these documents is indisputable, is undisputed; they are at once the most authentic and complete statistical documents extant. They are obviously medical in each and every particular; yet they do not emanate from the department to which they certainly belong, but from the War Office generally, and purport to be the work of a gentleman who, according to the date of the particular report which is referred to, will be found with the rank of Lieutenant, of Captain, and of Major; and when the next appears, unless he has achieved the next grade in succession, he will be found with that of Colonel. Now we are very far from desiring to call in question the merits of the successive Captain, Major, and Colonel; we only bid him in his prayers every night to thank God that he entered the army as an ensign, not as an assistant-surgeon. As an ensign he has thriven, he has risen according to his deserts,—not one step beyond them. As assistant-surgeon, with equal claims, he would certainly have been neglected and overlooked.

Who moved the gathering of the materials out of which these admirable statistical tables have been formed? and who actually gathered them? The Director-General of the Army Medical Department ordered, the army medical officers at large accomplished the work. Who showed how these bulky and incongruous materials were to be reduced to shape, to be brought into order, and made available for any useful purpose? Dr. Gordon first, in the offices of the Army Medical Department,

Mr. Deputy Inspector-General Marshall next at the War Office, having under him Assistant-Surgeon Dr. Balfour and Lieutenant Tulloch, as clerks and actuaries. Who has had the praise, who the profit of the labour, achieved when once fairly begun? Sir James M'Grigor's name is scarcely connected with the subject; if it be, 'tis but because it was impossible to omit it. Dr. Gordon has nothing that he had not before he meddled with the chaotic mass. Mr. Marshall, after some thirty years' service in all climates, gets a single step—from Deputy Inspector he becomes Inspector—and has some 5s. per diem additional half-pay, after he has put the reports in train, and made it easy for any one to follow in the track which he has indicated. Dr. Balfour, from assistant-surgeon in a marching regiment, after some ten or twelve years' fag as clerk, accumulates interest enough at head-quarters to get placed in the First Foot Guards, in *his old grade*, where he remains. Lieutenant Tulloch—ah! here we emerge from among the luckless family of the medici; here we come to fortune's favourite son at last! Lieutenant Tulloch by and by became Captain, and then Major, and then Colonel Tulloch,—all, doubtless, “as happy prologues to the swelling act of the imperial theme;” for we learn that he has only to live now to become General Tulloch; and should circumstances arise to make his services in the field more desirable than they are in the cabinet, no one can say to what worthy eminence he may not aspire;—and all this, we maintain, simply because Mr. Tulloch entered the army as an ensign, not as an assistant-surgeon. Entering as assistant-surgeon, the hill he has successfully clomb would have been as inaccessible to him as is the bottom in the middle of the Atlantic, five hundred fathoms down; the steep would have presented itself to him, only to

mock his eagerness and ability to scan it.

So much for the medical officer's chance of distinction in the army, where the duty that was rightly his, and that would have gained him credit, is taken from him, and given to another. Let us turn to the navy, and take the very last important feature in the history of navigation to illustrate our theme, that medical men are studiously neglected in the public service—we mean the lately returned scientific and exploratory voyage towards the antarctic pole, the fruit of which was the discovery of a new continent—Victoria Land—another world, ice-bound, indeed, and barren, but grand and striking in its physiognomy, as its discovery is gratifying to every better nature among us, from gaining us farther knowledge of the earth we inhabit. Of course all the officers engaged in the perilous service successfully achieved of circumnavigating the southern pole, were richly rewarded on their return. *Presque tous*, as the courtly preacher said when, suddenly recollecting in whose presence he was, he qualified the irrevocable doom that all should die—“*Nous mourirons tous—presque tous, Sire!*” So the officers of the Antarctic expedition were rewarded—*presque tous*. The captain was knighted, the commanders were posted, the senior lieutenants were gazetted commanders, the second lieutenants became first lieutenants, and a midshipman or two, we presume, were *made*. The surgeon of each ship, of course, got a corresponding advance. Not at all; neither of them got any thing. As they went out so they returned, so do they remain. And yet, will it be believed that the senior of these gentlemen voluntarily took on himself the office of zoologist and geologist to the expedition, was unwearied in his endeavours to collect specimens of fish, fowl, flesh, and mineral; and did actually make many ob-

servations and discoveries, zoological, geological, and general, of extreme interest to science, and, it may be, of vast importance to the commerce of this country—we allude to the discovery of coal—all of which were beyond the mere line of his duty, but attention to which on his part gave a character to the whole affair which has added immensely to its respectability, to its value and importance in the eyes of the philosopher and naturalist. Call ye that “backing of your friends,” my Lords of the Admiralty? Every officer, save the medical officers, promoted! Will it be believed? “Hath not a naval surgeon eyes, organs, affections like another man? Is he not fed with the same food, warmed and chilled by the same winter and summer as a captain, and commander, and lieutenant? If you prick him will he not bleed, and if you wrong and neglect him will he not repine?” Aye, marry, will he, and find unfettered pens, too, eager to aid him in giving shape to his secret sense of unworthy usage.

Surely the thing cannot have been seen in its proper light at the Admiralty, or such a grave slight would never have been put upon the whole medical profession as is certainly practised in this cruel neglect of the surgeons to the late antarctic voyage of discovery. It must be an oversight on the part of their Lordships, and needs only to be pointed out to be redressed.

BETHLEM HOSPITAL.

We have just learned incidentally that it was resolved unanimously, at the last meeting of the Committee, in addition to the numerous extensions and improvements that have taken place, and are still going on, within the walls of this noble institution, to increase the salaries of the physicians by the sum of £50 per annum; and farther, to add the amount of four pupils' fees to the whole, the tickets being placed at the

disposal of the Governors and medical officers of St. Thomas's and St. Bartholomew's Hospitals, to be awarded as prizes to the two most deserving pupils in each school respectively. The Committee of Bethlem Hospital are said to have it especially in view, by this wise and worthy liberality, to extend a knowledge of the pathology and treatment of insanity, and thus to make the establishment over which they preside a means of benefit to the public at large, as well as of advantage to the individuals who receive medical assistance, and now, in the majority of instances, recovered health within its walls. This is a truly noble spirit, and reflects the highest honour on the President, Treasurer, and Committee of Bethlem Hospital.

THE ST. MARYLEBONE INFIRMARY AND ITS MEDICAL OFFICERS;

TO WHICH IS ADDED, THE SKETCH OF A PLAN FOR RECONCILING DIFFERENCES, BY THE EDITOR.

To the Editor of the Medical Gazette.

SIR,

SEEING in your valuable journal some reference to the St. Marylebone Infirmary, as it was in the days of Dr. Hooper, and as it now is, and being well acquainted with the whole circumstances of that establishment, I beg to put you in possession of the following facts.

Dr. Hooper was the physician, and the late Mr. Phillips (surgeon to the household of George IV. and William IV.) was the surgeon. Dr. H. received £150, and Mr. P. the same sum, annually, as a *gratuity* (so it was termed), not a *salary*. In addition to this each received £30 per annum for visiting the insane at Hoxton. They were both allowed as many pupils as they chose to take, and Mr. Phillips a house-surgeon, who was lodged and boarded at the expense of the establishment, and paid Mr. Phillips £100 a year for the situation. The salary of the apothecary was £500 per annum, and he took two or three pupils, who worked in the surgery under his direction, and always paid him a handsome fee as his apprentices. This was the St. Marylebone Infirmary.

The change from what it was to

what it now is was very sudden. On the resignation of Dr. Hooper, a certain gentleman, who shall be nameless, persuaded some of the influential directors of the infirmary that the physicians of public institutions ought to receive no salary, and guaranteed that he would bring forward some who would do the work gratis. This tickled the ears of some of the directors, and they consented to try the experiment. The gentleman before alluded to canvassed several physicians; and under the specious promise that a school of medicine should be formed, they came forward and offered themselves as candidates. Two of them accordingly were elected "honorary physicians;" that is, with the understanding that they were to receive no remuneration for their services. The whole of the old staff were bundled out, *sans cérémonie*, at a moment's notice, and new "honorary" medical officers in every department were elected, whilst all the inferior medical offices were filled up at reduced salaries. So have things remained until the present time.

From this statement it will be seen that the directors took advantage of the competition that existed in the medical profession, to get their work done for nothing, and the example then set has been religiously followed by all Poor Law Unions, and by all classes of society ever since.—I am, sir,

Your obedient servant,
AN OLD DIRECTOR.

[Our correspondent, we opine, ought not to throw the whole blame upon the directors. It was unhandsome in them indeed to take advantage of any set of circumstances to get the necessary business of attending the sick poor performed free of expense; but the members of the medical profession ought to have stood out for fair remuneration; they ought not to have been found ready to cut their neighbours' and their own throats at the same time. We think the handsome thing for the directors of the Marylebone Infirmary to do now, is to come forward and address their present staff of very distinguished medical gentlemen in some such words as these:—"Gentlemen, we find that we have done wrong in yielding to the insidious suggestions of an enemy to your profession, by which we have been led to squeeze you of services that are necessary to us without making you any

return in the shape of gratuity, as of old. We have thought better upon the subject; we see that the labourer is worthy of his hire, and we have come to the resolution of reverting to former usage, and paying our medical officers for their services." Upon which the medical gentlemen ought to address the directors in these words, or in words to the following effect:—"Gentlemen,—We are of the same mind with yourselves; *we, too*, have erred in undertaking onerous and responsible duties without fee or reward, and are much rejoiced at the resolution to which you have come. We shall accept your money without any hesitation, and promise you to do our office not the less willingly and zealously for being paid." This we very humbly think would put all things right.]—ED.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, June 26th, 1844.

THE PRESIDENT IN THE CHAIR.

Tabular View of 180 Cases of Tubercle of the Lungs in Children, with some Remarks on Infantile Consumption. By P. HENNIS GREEN, M.B.

THE author commences his paper by observing that the remarks appended to the tabular view are rather intended to point out a few of the peculiarities which distinguish infantile consumption from the phthisis of adults, than to give any complete history of phthisis in the young subject.

The main character which distinguishes the phthisis of children from that of adults is this: in children the tubercular deposit occupies a much larger surface of the lung, is more rapidly secreted, and complicated with tubercular disease of other organs more frequently than in the adult.

Having briefly described the varieties of tubercular deposit in the lungs of children, the author gives some statistical results relative to crude tubercle and caverns, as deduced from his table.

The complications of pulmonary tubercle in the child are numerous and varied. The author compares his own results with those given by M. Louis for the adult, and shows the proportion in which various other organs were affected with tubercular disease.

The symptoms are referred to two varieties of the disease: one occurring in children of from 10 to 14 years of age, and resembling the disease in adults; the other affecting younger children, and presenting several

peculiarities. In the acute form of this latter variety, the patient is often cut off long before the disease has arrived at the stage of cavern, while the wide-spread and rapid diffusion of tubercular deposit may excite—in the head, hydrocephalus or meningitis—in the chest, pleurisy—in the abdomen, peritonitis—and in the intestinal canal, tubercular ulceration. In the chronic form of this variety, the author remarks that the signs of cavern are very frequently absent altogether, and this absence may depend on the seat of the cavity (middle or lower lobes), its anfractuous formation, or the small calibre of the bronchial tubes.

The author next examines successively the rational symptoms, and indicates the peculiarities which may attend each. With regard to hæmoptysis, he observes that it is not so rare a symptom as many eminent authorities assert. It did not, however, occur in any patient under nine years of age.

The question of diagnosis having been discussed, the author concludes with a brief description of bronchial phthisis. The mechanical and physiological effects produced by the enlarged glands on the neighbouring tissue and organs are first pointed out; the symptoms are then indicated; and the author sums up with some valuable remarks relative to the diagnosis of this variety.

The author does not enter into the question of treatment, which he regards as merely palliative; but he states his belief that, under favourable circumstances, we have a much greater chance of arresting the progress of incipient tubercle in the child than in the adult.

Peculiar Case of Gelatiniform Cancer, in which all the organs in the body contained Colloid Tumors: with the appearances on dissection. By JOHN C. WARREN, M.D. Professor of Anatomy and Surgery in Harvard University. [Communicated by MARSHALL HALL, M.D. F.R.S.]

THE patient in this case was a man aged 25. The particulars of it are detailed at considerable length, and could not be well abbreviated. The author remarks that colloid, gelatinoma or gelatiniform cancer, as it has been called, is stated by the various authors who have described the disease, as occurring in one single mass, usually of considerable size. Dr. Walshe says, "the comparative rarity of the coexistence of several tumors in the same subject has been noted in scirrhus; and that this is still more marked in the case of colloid. M. Cruveilhier states, that it is rare to observe its successive or simultaneous development in a number of organs or parts. Dr. Hodgkin expresses himself nearly in the same tone, but adds that it does at times invade different localities in the same subject." In the case here

described, the disease was diffused through nearly all the textures of the body, without presenting any one considerable mass. The author adds, that the case is also remarkable in exhibiting a union of the three admitted forms of malignant disease—scirrhus, cephaloma, and gelatinoma.

Case of Hemorrhage of the Liver. By JAMES ABERCROMBIE, M.D. Cape of Good Hope.

THE patient was a lady, æt. 35, who during the last two months of her pregnancy had suffered much from dyspepsia. On the 28th September, 1841, she was seized with severe pain at the epigastrium, a sense of distension, eructations, and nausea. Having on former occasions been relieved of (what she considered) a similar pain by pressure, she had recourse to it on this occasion, by bandaging the waist,—and to such an extent as to cause the author to fear mischief might be produced. Opium and ether were given, and in the evening she was quite relieved. On the following morning, however, labour came on; it was of short duration; the placenta was readily expelled, and the uterus contracted well. Within an hour, however, symptoms of sinking came on, which led the author to suspect uterine hæmorrhage; but on examination the uterus was found perfectly contracted, and the discharge outwardly very moderate. She complained of pain in the right hypochondrium, and right side of the neck. Opium and stimulants were freely given, and for a time she seemed to rally; but vomiting supervened, collapse of the system took place, and she died on the morning of the 1st October.

On examination after death, there was found on the anterior and superior surfaces of the liver a large sac, which burst on attempting to remove the organ, and discharged about two pounds of blood, fluid and coagulated. It was found to have escaped from a branch of the vena porta; and the sac was formed by the peritoneum. The organ itself had throughout a mottled appearance, and was unusually soft. The uterus was in a perfectly sound state, as were all the other viscera both of the pelvis and abdomen.

REPORTS OF CASES
OCCURRING AT
THE WESTMINSTER HOSPITAL:
WITH REMARKS,
By B. PHILLIPS, Esq. F.R.S.
(For the London Medical Gazette.)

EMMA YOUNG, admitted February 7th, 1844, under Mr. White; states that two years ago she had syphilis, for which she was

treated, at the Lock hospital, by mercury (to salivation) during seven weeks; since leaving the Hospital she has been living in a situation as a servant, and has been subject to pain in the head and limbs occasionally, for which she had taken the Decoct. Sarzæ Comp. with advantage; and that about three weeks previous to her admission into the Westminster Hospital, after exposure to wet, her throat began to be painful, with great difficulty of swallowing, which increased in severity so as to cause her to apply for admittance into the hospital.

On examining the throat on her admission, a large ulcer was observed over the back and sides of the pharynx, with considerable swelling in the surrounding parts; great difficulty of breathing, with occasional threatenings of suffocation; there was great tenderness over the larynx, cough, and almost a total loss of voice.

Ordered—Hirudines xij. laryngi app.; and the throat to be fumigated with Cinna-bar. Decoct. Sarzæ co. ʒiv. ter die.

9th.—Breathing rather better, complains very much of pain after fumigation, cough very troublesome, and constant vomiting.

ʒ. Mist. Acid. Hydrocyan. (mij.), ʒj. ter die. Discontinue fumigation.

10th.—Cough and vomiting relieved, but still great difficulty of breathing.

ʒ. Ung. Hydrarg. ʒss. nocte manequæ axillæ app.

12th.—Much the same; the ulcer in the throat is spreading, and looks in a sloughy state.

ʒ. Hyd. Bichlorid. gr. ij.; Sp. Vini, ʒss.; Aq. Destil. Oss. M. ft. Gargar. ter die utend.

15th.—Mouth slightly affected by the mercury, but without much relief to the breathing.

Cont. Med. et Gargar.

17th.—Cough very troublesome, occurring in paroxysms at intervals of a few minutes, threatening suffocation. To have a blister on each side of the larynx, and the throat to be touched with the following lotion:—

ʒ. Arg. Nitrat. grs. x.; Aq. Destil. ʒj. M.

20th.—But little alteration in the symptoms.—Cont. Med.

23d.—Passed a very bad night, being obliged to remain almost in the erect posture.

Cont. Med. et app. Hirudines vj.

26th.—No better; can now only swallow fluids, and that in very small quantity at a time; cough and difficulty of breathing much the same.

28th.—The same as last report.

March 3d.—Passed a very distressing night; suffocation is so imminent that it is evident, unless something is done to

relieve her, death will soon take place. The operation of tracheotomy was proposed, but Mr. White, wishing first to push mercury to the fullest extent, ordered her the following mixture:—

ʒ. Hyd. Bichloridi gr. ij.; Sp. Vini Rect. ʒj.; Decoct. Sarzæ Comp. ʒv.; Aq. Puræ ad ʒiij. M. ft. Mist. capt. coch. med. omni hora.

5th.—Continued the bichloride till she had taken gr. ix. in rather more than forty-eight hours, when there was profuse salivation, and all the symptoms of poisoning. The breathing and sense of suffocation are better.

6th.—Breathing better, but great pain in the stomach and constant vomiting.

ʒ. Acid. Hydrocyanici, mʒij.; Potass. Bicarb. ʒij.; Mucilage Acaciæ, ʒj.; Aq. Puræ, ʒiij. M. capt. ʒj. 6tis horis. Emp. Lyttæ epigast. app.

9th.—Vomiting relieved by the mixture, but the cough is again returning with its former violence.

12th.—Has passed the last two nights better, breathes quietly during the intervals of the cough; can swallow better; bowels confined.

To have an aperient draught of Pulv. Rhæi et Mag. Carb.

16th.—Continued rather better until to-day, when she complains of great pain on the left side of the larynx, and that she was frequently awakened in the night by violent paroxysms of coughing and sense of suffocation.

Ordered to use again the Ung. Hydrarg. and take a dose of cough mixture frequently.

20th.—Swallows with greater ease, but cannot sleep at night; cough and breathing rather better.

25th.—Was attacked during the night with rather severe diarrhoea.

ʒ. Tr. Opii, mxx.; Mist. Cretæ Co. ʒiv. M. capt. ʒj. frequent.

29th.—Is rather better; cough troublesome at night; the ulceration in the throat is gradually spreading.

Ordered to again use the Cinna-bar Fumigation, and Decoct. Sarzæ Comp. ʒj. ter die.

April 4th.—Much the same as last report.

10th.—Her general health is much improved; appetite good, but cannot swallow any solid food; cough and breathing better; cannot speak above a whisper.

15th.—Improving in health; the ulceration looks more healthy, and is less extended.

20th.—Better.

26th.—Gradually improving in health;

throat better; can now swallow with less pain.

During the months of May and June the patient has been gradually gaining strength, and the ulcer closing: she can now take solid food without much inconvenience, but the voice is only a whisper. She has been again placed under the influence of mercury, during which the voice is much more distinct; but, as soon as its action ceases, the old state of things returns, and the voice is as weak and low as before.

REMARKS.—In the preceding case I am of opinion that the best course to have followed would have been to have performed tracheotomy at the first favourable moment after admission. It was evident that the inflammation, and probably the ulceration, extended into the larynx: the complete aphony, the tumefaction, and pain upon pressure in the left side of the larynx, go far in proof of that view of the case. It was scarcely possible to conceive a worse state of things, in a condition like hers, than the existence of constant laborious respiration, increased many times a day almost to suffocation. It is a matter of astonishment that it had not destroyed life, and the fact that it did not was no proof that the operation of tracheotomy was not, under all the circumstances, the best course to have followed. In itself, it is not a dangerous operation; the vast majority of cases in which it has been done have been successful in as far as the operation is concerned; but it is usually done when the mischief has gone too far to be relieved by any means. In the present case it would have left the parts at rest, and given the means used a fair opportunity of assisting in their restoration.

The ulceration was always decidedly syphilitic in its character, but on her admission the irritability of the surface was so great, and the bodily strength so broken, that I thought it better to give her the Decoct. Sarsæ, to introduce mercury by small inunction, and apply it in the form of fume upon the ulcerated surface, hoping that it might allay its irritability. The good expected did not result from the plan; matters then became urgent; and Mr. White preferred the very vigorous use of the bichloride to tracheotomy. On the second day, when she had taken nine grains, the deleterious action of the remedy upon the system was developed, but there was a remission of the urgent local symptoms; and from that time there has been a gradual amendment: there have been many severe drawbacks, but relief has been afforded by mercury in some form. It is surprising how strong a hold syphilis possesses on some constitutions, how difficult it is to eradicate it. In this case generous feeding; sarsaparilla, iodide of potass, were fully tried, but without success;

and even mercury, which has always been useful, it has been found necessary to repeat again and again.

At present the breathing is quiet; deglutition is now performed without pain; there is some little chronic inflammation left; and there are indications of restoration of the voice. She is able to take exercise every day in the open air, and may now be regarded as convalescent.

George Johnson, æt. 53, admitted into Mark ward, Feb. 28th, under Mr. White, suffering from extravasation of urine. About a week before admission, after having drunk to excess, he had retention of urine, which was quickly followed by pain and swelling in the perineum, and inability to move. On examination, there was a hard tumor occupying the left side of the raphe from the penis to the margin of the anus: it is very painful to the touch, and when he moves. The urine passes freely; pulse low and weak; no appetite.

Ordered to apply warm fomentations, and to take the following mixture:—

℞ Liq. Amon. Acet. ʒj; Sp. Æth. Nit. ʒss.; Mist. Camph. ad ʒvj. M. cap. ʒj. 4tis horis.

March 1st.—Has had several attacks of shivering during the night, but there is no fluctuation. To take at bed-time—

℞ Hyd. c. Cretà, gr. viij.; Pulv. Ipecac. Comp. gr. xij. ft. Pulv.

2d.—Much the same as yesterday, but very low.

Rep. Pulv. h. s. s. et Ol. Ricini, ʒvj. cras mane.

Several incisions were made by Mr. Phillips into the swelling, and a considerable quantity of pus and urine escaped.

3d.—Urine having escaped into the cellular tissue of the scrotum, incisions were made in several parts of it. Pulse very low and weak; skin of a yellowish hue all over the body; and, notwithstanding the extravasation, he passes his urine by the natural passage without pain or difficulty.

℞ Vin. Rub. ʒij. 6tis horis; and yeast poultice to the scrotum.

4th.—Fresh incisions were made to-day, the urine having infiltrated the whole of the scrotum. He is very low; the skin is now become of a dark jaundiced colour; there is occasional delirium and insensibility, and when roused he complains of numbness in the lower extremities; the feces pass unconsciously.

Ordered Gin, ʒj. 3tis horis; and as much beef-tea as he can take.

℞ Hyd. c. Cretà, gr. vj. 4tis horis.

5th.—Is much the same as yesterday: a considerable quantity of urine has escaped both by the urethra and the incisions.

Continue the Gin and the Hyd. c. Cretâ; and take at bed-time, Hyd. c. Cretâ, gr. viij.; Pulv. Ipec. Comp. gr. x.

6th.—Passed a good night, and is much better; the bowels have not acted since yesterday.—Cont.

7th.—The whole of the integuments of the scrotum and perineum are in a sloughing state. Urine passes freely.

9th.—Continues to improve. Bowels rather confined.

To take a dose of Castor Oil, and continue the Hyd. c. Cretâ.

10th.—Bowels relieved twice by the oil naturally.

13th.—Improving.

Cont. Med. mutton chop, and gin, ziv .

16th.—Has not been quite so well the last two days, being hot and feverish; slight headache.

Ordered—a saline effervescing mixture, and to repeat the castor oil.

20th.—Is a good deal better; bowels regular, and passes urine freely, although in a small stream.

Cont. Med.

24th.—General health much improved, the sloughs are beginning to separate, and he is free from pain.

Omit half the gin, and take Oj. of porter daily.

28th.—The slough has completely separated, and left a clean healthy wound; appetite good, and passes urine freely by the urethra.

April 1st.—Going on well. A small catheter was passed down to the stricture, but could not be got into the bladder. He is now able to get up for a short time during the day.

5th.—Rapidly improving in health; wound granulating.

8th.—Doing well; catheter passed into the bladder, and allowed to remain several hours.

11th.—Doing well.

15th.—Doing well.

His health was gradually re-established, and the wound quite healed when he left the hospital in May, with directions to attend twice a week for the purpose of having the catheter passed.

REMARKS.—The point of interest about this case is, that except for five or six hours the patient has always been able to pass his urine freely: not so much so as when in health, but sufficiently so to empty the

bladder, and the calls to do so were not very frequent. Still it is evident that a diseased and contracted state of the urethra did exist, and that the urethra did give way during the complete retention, which occurred after his debauch. It is the practice of some surgeons to treat such cases by introducing a catheter whenever the patient requires to pass his urine; of others to let the catheter remain in the urethra, in order to prevent it passing by the wound, and thus establishing a fistula. That course was not followed in this instance, because the urine passed freely by the urethra, but little escaping by the wound; and because the man's condition seemed so desperate, that the irritation of frequently passing or wearing a catheter would be a much greater evil to him than allowing some urine to pass through the wounds. Gradually the whole of the urine passed by the natural channel; and before any plan of dilatation was put in use, the urine had ceased to escape through the perineum.

COMPLETE EXTIRPATION OF THE UTERUS BY LIGATURE,

AFTER CHRONIC INVERSION OF THE ORGAN.

By Dr. JOHN M. ESSELMAN, of Nashville.

A LADY, 32 years of age, married 14 years, had been in bad health ever since the birth of her first and only child, twelve years previously to Dr. E. being consulted. She had been attended in her confinement by an old woman; her labour was a protracted and painful one; she had flooded profusely, and was very ill for several weeks after her confinement. After she was able to leave her bed and walk about the house, she was much annoyed by "*bearing-down pains*," as she called them, in the region of the womb, extending up in the direction of the lateral ligaments of that organ. She had also suffered much from pain and weakness of the back, and also from pain and a numb sensation down the inner portion of the thighs, and had been a prey to fluor albus ever since she had left her bed of confinement. The menstrual discharge was often very profuse, indeed alarmingly so; that she would be confined to her bed for weeks, take medicine to check the hæmorrhage, &c.; then she would be put on the use of tonics, to strengthen her system, as well as to correct the fluor albus. At length she was advised by her physicians that she was labouring under prolapsus of the womb, and underwent the routine of treatment in such cases; but all to no effect, except the relief she invariably obtained from the horizontal position.

Disheartened by the little relief she received, she went to Nashville, where she consulted a

distinguished practitioner, who diagnosed a polypus, and he applied a ligature, which was productive of such alarming symptoms that he removed it. Various other medical men were consulted, but without relief being afforded.

When Dr. E. was consulted, he found her in a deplorable situation; she was labouring under hectic fever, had profuse night sweats, hacking cough, and all the symptoms indicative of a rapid decline. On examination, he found a tumor occupying the vagina, about the size of a large pear, and answering in every respect the description usually given of a polypus. The vagina itself was very irritable and much ulcerated, so that it was impossible to make a very minute or satisfactory examination. However, from the history of the case, and the opinions of other medical men who had examined it previously to himself, in some of whom he had the utmost confidence, he concurred with them that it was a polypus. But being at that time a young practitioner, having been but two years in the profession, he requested that some other physician should be called in to assist him in the operation. An intelligent practitioner was accordingly called in, who took the same view of the case; and after a few days of preparatory treatment, a ligature of saddler's silk, well twisted and waxed, was applied; a full dose of camphor, laudanum, and hartshorn having been administered two hours previously. The tightening of the ligature gave great pain, and the dose of camphor, laudanum, and hartshorn was repeated. For the first four or five hours she was very much prostrated, and her pulse sunk to a mere thread; she, however, then became composed, reaction took place, and she rested tolerably well the first night. The ligature was tightened every morning for eighteen days, at which time it came away, and, to the surprise of her physician, instead of a polypus, the tumor proved to be the uterus itself, much reduced in size by ulceration and strangulation. The vagina was much ulcerated, and emitted a very offensive sanious discharge, for which frequent injections of a solution of chloride of lime were ordered, and a solution of nitrate of silver was applied to the ulcers. The general system was sustained by tonics, such as the muriated tincture of iron, phosphate of iron, quinine, &c., and a generous diet, when the absence of febrile excitement would admit of it. She was a long while recovering, and did not leave her bed for months after the operation, but finally was restored to perfect health. For the last twelve months after her recovery she required frequent bleeding and purgatives to relieve headache and a tendency to vertigo, as well as a general plethora of the system, occasioned, Dr. E. thinks, by the

"premature suspension of the catamenial secretion."—*Western Med. & Surg. Journ.* Aug. 1843; quoted in *American Journal of Medical Science*, Jan. 1844.

THE BANAT FEVER IN HUNGARY.

TEMESVAR is the most important town in the whole Banat,—the principal place of residence of the Servian nobility of the province, and the head quarters of the Banat fever. All along the road I had been told, "When you come to Temesvar you will see what the fever is. The people there creep about with pale faces, and almost every one you meet is an invalid." This account I found literally true. At the very entrance of the town I met a waggonful of these poor fever-sick people, who, I was told, were going outside the town to look for a certain herb, supposed to be more efficacious as a cure for the fever, than all the doctors' medicines. After driving through a long suburb, and across a broad marshy glacia, I at length reached the inner kernel of the fortress, and stopped at a very excellent inn called "The Trumpeter," whence I went to pay a visit to an official personage, to whom I had a letter. His valet came to me with a slow heavy step, and a dejected look, and begged I would be so good as to call the following day, as his master had the fever, and was just then in a paroxysm in bed. I asked what was the matter with himself, that he seemed so cast down? "Ah, sir," he replied, "I've got the fever too." From this house I proceeded to another, where lived a lady, to whom I was charged, by some friends in Vienna, to pay my respects. "Oh, sir," said the waiting-maid, "my lady has had the fever these three years, and she is just now at her worst." Opinions are very various as to the cause of this distressing malady. By some it is ascribed to the fruit, especially to the water-melons; by others to the bad water; by others to the marshes, where arise that other plague of the country, the gnats. The latter opinion seems the most probable, when the position of the town is considered. It lies, notwithstanding its name, not on the Temes, but on the Vega, in the midst of the many marshes which the latter stream forms. In summer, the heat is suffocating, and for weeks together there is sometimes a perfect calm. An attempt has been made to remedy the evils by means of a canal, twenty German miles long, which serves not only to drain the country, but from Temesvar downwards is used for the purposes of navigation; but one canal is quite inadequate to meet the extent of the evil. The country must be intersected in every direction, like Holland or Egypt, before any good can be

done. In this extremely hot summer the fever had been dreadful. The inner fortress of the town felt like a baker's oven, and the air was so close and sultry that a person coming in from the country could scarcely breathe in it. The great majority of the population had been attacked by the malady, and even those who were said to be free from it felt more or less unwell. Of the two thousand soldiers of the garrison, nine hundred were in the hospital in one week, and there they had to lie or stand, and get through the fever as well as they could. The garrison became at last so enfeebled that it was found impossible to get through the ordinary duty. This Banat fever exhibits itself under forms as various as the gourds and melons that grow in the country. With some the attacks occur every day, with others every night. In some cases it appears as an intermittent fever, but the attacks return sometimes every second day, sometimes every third or fourth day, and these are said to be the severest cases. The symptoms also vary in almost every instance, some being attacked the very day they enter the city, others not till they have lived in it a considerable time. A journey to Pesth will often rid a man of his fever, but this rule is liable to exceptions, as there are persons who have left the country, and yet retained their fevers for years. During the first days of my stay at Temesvar, I could absolutely find nobody who was free from fever, so I resolved to employ some time in rambles about the city and environs.—*Kohl's Austria, English translation, p. 307-8.*

SECTION OF THE EIGHTH PAIR.

M. BERNARD has instituted some new experiments upon this interesting physiological question. Having previously established a fistulous opening into the stomach in the subjects of his experiments, he could observe with great advantage all that happened on the division of these nerves. His conclusions are—1st, that division of the pneumogastric nerves is followed by the extinction of all sensation and motion in the stomach; and more than this, by a complete arrest of the secretion of gastric juice. 2dly, by an entire suspension of the digestive function; pieces of meat put into the stomachs of dogs whose pneumogastrics had been divided were found twenty-four hours afterwards totally unchanged. 3dly, in the absence of the gastric juice, spontaneous changes take place in the food in the stomach.—*Comptes Rendus, Académie des Sciences, 27 Mai.*

IMPORTANCE OF CHEMISTRY.

FORMERLY the chemist went to the soap-boiler, to the tanner, to the manufacturer and artisan, whereas at present the soap-boiler, the tanner, the manufacturer, and artisan, frequent our universities; because

they know that it is science alone which can furnish them with the master-key, the magic spell, the "open sesame," to unlock all the mysteries of their pursuits. Just as at the present day the influence which the application of chemistry will exercise upon the solution of physiological and pathological emblems, is by many physicians considered worthy only of ridicule, so formerly were the advantages derived from chemistry to arts, manufactures, trades, and agriculture, when first indicated, only laughed at by those who were pleased to call themselves *practical men*.—LIEBIG, in *Lancet* of June 29th.

NEW FELLOWS OF THE COLLEGE OF PHYSICIANS.

Drs. Plenderleath (of Ramsgate), Forbes, Conolly, Ramsbotham, Cursham, Hughes, Rees, and Guy, have been elected Fellows of the Royal College of Physicians.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Gentlemen admitted Members on Friday, July 5.—H. F. Middleton.—J. H. Llewellyn. G. C. H. Hitchings.—J. Mitchell.—D. J. Allen.—J. Ozanne.—R. J. Loch.—N. S. Glazebrook.—J. E. Hebblethwaite.—C. W. Hope.—J. H. Smith.—T. Blatherwick.

MORTALITY OF THE METROPOLIS.

Deaths from all causes registered in the week ending Saturday, June 29.

ON
MILITARY HYGIENE,
AND PARTICULARLY UPON
THE CLOTHING OF SOLDIERS.

By FREDERICK ROBERTS, Esq.
Assistant-Surgeon 59th Reg.

(For the London Medical Gazette.)

As the subject of the physical condition of soldiers has hitherto received little attention, I propose to offer a few remarks upon one of the most interesting problems in the range of medical inquiry.

The observations about to be embodied will not bear with them that demonstration which statistical documents convey upon many points; the opportunities, documents, materials which could afford me the information, being, I regret to say, beyond my reach. Without indulging in conjecture, it will be attempted to be shown, however, upon physiological and anatomical principles, that the dress of the British Infantry soldier exerts an injurious influence upon the health of the man. In considering the dress of the soldier as one of the agencies which contributes to his ill health, I must observe that it is not so much the dress, *per se*, which I consider so injurious, as it is the peculiar position and nature of the occupation under which it is worn. If worn by other members of the community, it might not be so hurtful as it is to the soldier, whose occupations make it prejudicial to the wearer. In inquiring into the influence of the dress of the soldier upon his health, it must be examined under the circumstances of his various duties and positions; but as these are so manifold and dissimilar, I can but slightly notice them without some digression, which it will be best to avoid, and on another occasion make them subjects of separate inquiry. The physical condition of soldiers is materially different from that of the labouring man generally, and the ill effects of it are

greater than they would be upon the civil community, which is not subject to the same legislation as the military.

It will be remembered that, under the most favourable circumstances, mortality and ill health are greater in the army than in any other community. It is wrong, therefore, to suppose that misery (in its usual sense), with its accompanying privations, is one of the most influential causes of mortality, as it is needless to say, however anomalous it appear, that soldiers are *not miserable*. To suppose that soldiers recover from syphilis without mercury, through the strength of their constitution, is equally a fallacy. They are neither strong nor healthy. Of the select troops of the British Army serving at home, 40 out of 1000 are constantly sick; 26 out of 1000 are, on the average, among the same, annually invalidated as unfit for service, and out of 1000 chosen men of the household troops and foot guards, 18, on the average, annually die.

In reviewing the several physical relations of the soldiery, it will be seen that the laws of physiology are more violated in regard to them than to any other community, and that their health and lives suffer more from enactments in opposition to the structure and functions of the human body. Towards the amelioration of the physical condition of the soldier, I believe the most beneficial and practicable step that could be taken would be the improvement of his dress. The changeable and irregular mode of life of the soldier must satisfy us that his body is necessarily more than usually exposed to the operation of various natural agents, with which we are constantly surrounded, and which exert an unceasing influence in the production of disease. To give a lengthened exposition of the influence of the physical agents on the animal economy is not my intention, as, indeed, it is not necessary; but to show to what varying intemperatures the soldier is subject, I shall give a brief sketch of the routine of his ordinary duties.

The soldier will generally, if not always, be seen in the barrack-room with his jacket open, employing himself in the morning in making up his bed, and preparing for parade, &c.; after which his destiny is so various that I must follow him somewhat particularly. In a dress inimical to the natural motions of the muscular, respiratory, circulatory, and cutaneous systems, in hot, cold, wet, or windy weather, in the tropics or cold regions of the north, he falls in on parade, undergoes inspection, and executes manœuvres for a period varying from fifteen to sixty minutes on ordinary occasions; but when large bodies parade, this period often extends to two or three hours. On sentry, he is, to a more or less extent, liable to exposure to a hot sun in a tropical climate, and perhaps to severe cold at night; at any rate to extremes of temperature. In other climates nearly the same exposures await him. When relieved off sentry, he goes into a guard-house, sometimes crowded, and finds himself obliged to go out for fresh air again. At night, or in cold weather, he is perhaps unable, by walking to and fro, to keep up his natural heat, the constrained position of a sentry under arms being unfavourable to the preservation of his warmth. After relief at night, he falls into a sleep in this chilled state on the Guard-room bed, consisting of bare boards, and awakes with a cold or rheumatism—his power of generating heat to resist the effects of direct and continued application of cold being least energetic whilst asleep. When on guard, which he mounts for twenty-four hours, "no soldier or officer is on any account to take off his clothing or accoutrements." Again, after a drill or a march, in heavy marching order, he is seen immediately to strip off his coat, or to throw it open, and to employ himself in some sedentary work, as cleaning his fire-lock, accoutrements, &c., whereby he is further exposed to the influence of cold, which has great effect upon the body, which, from a state of active circulation and perspiration at drill, &c. relapses into that of passive quietness and repose. Exclusive of the irregularities he may cause himself to be exposed to, the very nature of his occupations renders him liable to every vicissitude of weather. The well and the badly-behaved are equally exposed, but the latter particularly so: when found drunk, the soldier is put into a dark and often damp cell for the night; and upon conviction of crime, he is probably sentenced to the same dungeon for an indefinite period, or to drill in heavy marching order, carrying upon his person some sixty pounds weight, the greater part of which is lashed about his chest by numberless straps, for periods varying from two to six hours daily, and from one to forty days. In military prisons, upon a scale of

diet lower than in civil houses of correction, his present undress is not capable of supporting a sufficient degree of warmth in his system.

Before entering into a description of the dress of the soldier, and its injurious tendencies, it must be mentioned that, as the soldier seldom complains, it cannot be hurtful. He is seldom able to judge of its qualities. Because glaring mischief is not perceived to follow *instantly* every breach of an organic law, it is no wonder that we should suppose there is no harm done; and because the thing is constantly before our eyes, that it cannot be bad. "Men seldom inquire into things constantly before their eyes. Habitual acquaintance prevents that curiosity which is one of the greatest incentives to knowledge." Although there are agencies from which we shall never be able to protect ourselves, yet attention to different safeguards may ensure tolerable health; as is seen from the diminished mortality since the increase of knowledge of physical science.

That the defective clothing of the soldier is the chief cause of his ill health, will, I think, be made evident; but to suppose that it alone gives rise to so much disease is not maintained. Consequent upon the physical relations of the soldier, his defective clothing bears the greater share in the production of disease. To assist him in his duties, his habitation must be good, dry, and properly ventilated, and his diet nutritious; against defective habitation, and indifferent diet, the principal preservative appears to be an efficient dress. And the deteriorating influence of duties may better be obviated by attention to the clothing of the soldier than any alteration in his habitation or diet. To suppose that the existence, and degree of virulence, of an epidemic depends upon some one hidden cause, exclusively, is unphilosophical: the history of medicine shews that not only may the influence of an epidemic be modified, but often materially avoided, by attention to physical comfort. The crews of some ships of war have been known to avoid the yellow fever for long periods in the West Indies, by recourse to the precaution of wearing flannel, and by attention to other healthful means suggested by intelligent commanders.

It would be interesting to inquire into the relative prevalence of consumption in those well and badly clothed; but even supposing this ascertained, it would not settle the question, inasmuch as the generation of heat in the body would not be in proportion to the amount of clothing worn, but in the ratio of exercise taken by the individual in his occupation, to insure freedom from mischief to the lungs in the way of congestions and partial chronic inflammations of the pleura, &c. It is a fact, however,

that those whose circumstances are the best in the world, or whose circumstances are such as to protect them the better from cold, are the most free from tubercular disease. Sir James Clark says that "there are certain trades which are unfavourable to the occurrence of phthisis; among these, seamen, butchers, and tanners, hold the first rank. It has been imagined that there is something in these occupations which has a special effect in preventing the development of tubercles, arising, in the one case, from impregnation of the atmosphere with saline particles; in the other, from peculiar properties in the atmosphere when impregnated with effluvia from dead animal matter or living vegetables. We have no belief in the special effects of such agents, but refer the exemption of these classes chiefly to the free and regular exercise in the open air which they enjoy." The occupation of sailors is such as secures to them a tolerable degree of warmth; they are on watch for four hours at a time; during this period it is seldom, in wet and blowy weather, that they have not some work to exercise their frames and prevent chills; and when not so employed, a sailor walks smartly up and down the deck, wrapped in a P-jacket, and is not restrained from freedom of action, altogether impracticable to a soldier on sentry, and who, with a fire-lock, is bound to observe a certain *prima* carriage and formal demeanour, in a constrained dress, little calculated to resist the impression of cold. The sailors of the Royal Navy are prone to acute catarrhs, from sudden but short exposures to cold, which do not degenerate into organic lesions, from their facility of exchanging their dress soon, and from their not being subject to the *passiveness* of habit of the soldier. Butchers are as well dressed as other people, lead a bustling life, do not stand much in the same position, have exercise for the greater part of the muscles of the body, plenty of air, and are protected from the wet: they are eminently in a position to resist cold. Tanners work with their coats off and shirt-sleeves tucked up, have their upper extremities in constant action, move about, are under cover chiefly, and their systems are favourable to *re-action* when exposed to the impression of cold. Smiths are observed to be exempt, in a great measure, from consumption—the result, probably, of keeping up constant action in the skin by the exercise of the arms, and by the warmth of habitation, and never being chilled, when working more leisurely, by reason of the heat of the smithy.

Women are more subject to consumption than men, a circumstance attributed by the learned "chiefly to lacing the chest." Although I believe this to a considerable extent, I am sceptical as to its being the sole

reason of the difference in liability to phthisis. Women, from difference of formation, I conceive not to suffer so much from lacing the chest as from exposure to cold by the nature of their dress, which partially exposes their chests, and but indifferently protects their lower extremities. Add to this, likewise, their *passiveness* of habits. Tight lacing prevails more in the higher and middle classes of life, but consumption in the lower, who are worse clothed. Whether, amongst the majority of the women of England, any alteration of form occurs in the frame from lacing, is a question that cannot be answered, but I am inclined to say no. There is greater facility of motion in the respiratory process in the female than male, from looser and slighter disposition of muscle about the bony structure of the chest, and from the relative larger capacity of the abdominal cavity—all permitting easier expansion of the lungs than in the male. The tight waistband, the braces, and close-fitting coat of the European male, I contend is but a trifle less injurious than the corset of the European female: in the former, elevation of the chest during respiration is impeded a good deal, and expansion suffers in some measure. In persons already diseased in the chest the injury is obvious. In the female, elevation is not so much arrested, but expansion is, and produces, in my opinion, not more injury than the united effects of imperfect elevation and expansion in the male. In Mahomedan countries, where men and women wear garments of thick material, and cover the chest well, but not constricted by tight coats and stays, pulmonary consumption appears to be a rare disease. In Dr. Holt Yates' Report of the British Dispensary in Syria, out of 4298 admissions of all diseases, only 284 cases of pneumonia and bronchitis occur, and none of phthisis! In England and Wales, in 1838, the Registrar-General shews that 27½ per cent. of the total deaths were owing to diseases of the respiratory organs!

Sir George Lefevre, in his book upon the advantages of thermal comfort, says that it is proved by the bills of mortality that one-fifth of the population dies of consumption in the British Isles, whereas the deaths in northern latitudes are *infinitely fewer* from that disease*. Whence this anomaly, that cold—being, as we believe it to be, the great exciting cause of such maladies—should have so little influence upon human life where it prevails in so great a degree? The secret is to be found in the fact that cold, in the northern realms, spends its fury upon vegetable life and inanimate matter, so that only certain species of plants can resist its influence.

* Sir George Lefevre practised a long time in St. Petersburg.

"That animal life would as soon perish is equally evident, but animal life is not exposed to it. The bear, covered by his non-conducting and impenetrable fur, covers himself up under warm leaves; the hare buries himself in the snow, the wolf finds holes, and the fox procures dens; and domestic animals, and those which are necessary to man, are provided with warm habitations. The human species is protected by clothing which once protected the animal from the same influence. It is not correct to suppose that the Laplander and the Samoide are impervious to cold, or become accustomed to it: that is an error. They are more susceptible of cold than the inhabitants of more temperate zones; but they do not expose themselves to it. This circumstance surprises strangers during their first winter's residence in Russia; they are astonished to find the natives enveloping themselves in warm clothing at the commencement of autumn, when their own moderately warm dress proves quite sufficient for them. What astonishes them at the commencement ceases to do so in time. As they sojourn longer in the climate they feel the cold less, inasmuch, only, as they are better provided against it. They do not get accustomed to the cold, but to the custom of the natives, who never brave it but by dire necessity.

He further remarks, that the peasant does not resist the cold from constitutional animal power, but from artificial protection against its influence. The Russian peasant's hut is insupportable to those who are unaccustomed to such indoor temperature. Those in easier circumstances sustain the cold, on quitting their warm rooms, by enveloping themselves in fur-pelisses, whose non-conducting qualities will neither suffer animal heat to escape, nor cold to penetrate from without. "Heat breaks no bones," is a Russian proverb, used when your rooms are accused of being warm.

At the Cape of Good Hope, where consumption is a rare disease, the natives wear leather and flannel clothing. The soldiers, who are nearly equally free from consumption, wear leather trowsers, and probably flannel like the natives. The duty of the soldier in this colony differs much from what it is in garrison towns—the men are detached in small bodies along the frontier chiefly, and their night duty is only patrolling—a work which may keep them out of bed a good deal perhaps, but certainly not more, if so much, as when in garrison; and a sort of work which is more active, and not so prone to chill the body as standing on sentry, and sleeping on the boards of guard-beds in clothes and accoutrements. Exemption from tubercular disease at the Cape is not, however, solely attributed to the superior clothing and nature

of duty of the soldiers; but it is necessary here to notice the facts. "What keeps the warmth in keeps the heat out," is a proverb among the Boors, who wear their thick clothing even in hot weather.

It has been mooted lately that phthisis finds its antagonism in marsh miasma. The Boors are descendants of the Dutch, who inhabit a marshy country. It would be curious to ascertain whether the Dutch in Holland wear thicker clothing than their neighbours, and thus derive, in part, their exemption (if they do) from consumption, and which is too evidently possessed by their descendants at the Cape.

It would almost appear that I should advocate natives of a cold climate to be more free from consumption than those of a warm one, when I mention that the ratio of deaths, among soldiers, from consumption, is less in North America than at home; but it is to the very superior clothing of the soldiers in the Canadas that this must be attributed—they being there provided on the approach of winter with "two thick flannel shirts or waistcoats, two pair of flannel drawers, a pair of cloth overalls, fur cap, woollen mits, galoshes, or moccasins, and in the lower provinces, a thick cloak to be worn over the great coat when on duty."

The cavalry at home are less exposed to inclemency of weather, and are better clothed than the infantry; the former being generally provided with flannel waistcoats and drawers, which are not supplied to the latter.

Major Tulloch's Report shows the difference of mortality in the cavalry and infantry to be as follows:—

	Per 1000 of Strength.
Household Cavalry	14·5
Dragoons and Dragoon Guards . .	15·3
Foot Guards	21·6
West India Depôts	18·5

The ratio of deaths from diseases of the lungs, per 1000, in these different troops, is as follows:—

Household Cavalry	8·1
Dragoons and Dragoon Guards . .	7·7
Foot Guards	14·1
West India Depôt	9·6

It is interesting to remark that rheumatism should be less frequent in the Canadas than in the West Indies, the Cape of Good Hope, and at home. The following from Major Tulloch's Reports shows the relative prevalence of the disease in the different commands:—

	Annual ratio of admissions with rheumatism, per 1000 of mean strength.
Upper and Lower Canada	40
Windward and Leeward Islands . .	49
Cape of Good Hope	57
United Kingdom	50

The prevalence of rheumatism at the Cape is exactly what we should expect from the nature of the patrolling duty, which renders the men liable to be affected by sudden cold and wet. But as this cold and wet is of short duration, and does not chill the body for any continuance, and by walking smartly the body is capable of reacting quickly, and so keeping up tolerable warmth in the skin, which sympathises so much with the lungs.

Instances of the effect of cold upon animal life may be greatly multiplied. It is proverbial that invalids in returning from warm countries die very numerous in approaching the colder latitudes, and when storms and cold weather happen at sea. It is further an ascertained fact, that negroes, monkeys, and parrots, on coming into cold climates, die greatly from tubercular diseases.

Organic diseases, as consumption, structural derangement of the heart, large vessels, liver, intestines, &c., are of frequent occurrence among soldiers. They are observed to be so predominant that Dr. Davy remarked their prevalence among diseases of soldiers, and broached the idea of an "*organic constitution*" in certain seasons and years. If the inquiry was further extended, I think that this *organic constitution* (if it may be so called) of Dr. Davy's would be found *always* to prevail in the army. Soldiers die from diseases foreign to those they are admitted under*. Examinations after death discover the alarming extent of tubercular disease, as is observed in the *Necrological Journal* at the Invalid Dépôt at Chatham, and in regimental records.

Diseases of the liver are more prevalent in soldiers than sailors of the Royal Navy; but in neither service are they supposed to be a source of much inefficiency. Reference to the autopsies made in the army I think would show that many men, who die under the head of another disease, say intermittent and remittent fever, dropsy, &c., suffered from diseased liver, and which probably killed them. Taking, however, the present returns to be correct, and to show that I have some reasons to believe that more soldiers die tubercular than supposed, I have to mention that there is great connexion between phthisis and hepatitis. In 49 cases of fatty degeneration of the liver, Louis found that 47 were phthisical.

Organic diseases of the brain, heart, and large vessels, are of frequent occurrence among soldiers, as will be seen from the tables of their diseases. When the opportunity arrives, I purpose shewing more posi-

tively that this is the case, and to shew how far they may be referrible to physical causes, capable of being modified. This, however, I must postpone till I enter upon another subject in illustration of the physical history of the soldier.

Without noticing what influence the auxiliaries of bad ventilation, crowded habitations, and intemperance, may exert, the peculiar posture of soldiers, their confined dress, occasional violent exercise in tight clothes, with cross belts and knapsack, are eminently calculated to prevent free exercise of the pulmonary organs, to diminish the powers of the system, to impair the nutritive functions, and are fully adequate to produce premature senility, which is so conspicuous in the soldier, and which may be regarded as a constant effect in a greater or less degree.

The effects of direct application of great heat to the head, soldiers are liable to, from having little or no rim to the cap, and from the constriction which the same article of dress exerts round the head, he has often suffered from coup-de-soleil; at other times, the foundation of organic derangements about the brain, or its membranes, have certainly been laid. In one action in China, thirteen men of one regiment, lately arrived from home, and which entered the field buttoned up to the throat with leather stocks and forage caps on, fell down dead.

[To be continued.]

REPORT

ON THE

ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from p. 487.]

DURING the year 1843, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2002 women—Of which cases,

23 were twins—about 1 in every 87 cases: of these in 15 cases both heads presented; in 6 the presentations were head and breech, or some part of the inferior extremities; in 1 both were feet; and in 1 the feet and the shoulder. In 10 of these cases both children were boys; in 6 both girls; and in 7 of different sexes. One of these children was delivered by "turning" two hours after the birth of the first. It was born living.

1037 children were males.

968 children were females.

* As this, I am sure, occurs to a great amount in the army, and as the name of the disease is not changed in the returns, considerable uncertainty in the character of the statistical evidence of Army Medical Reports must exist.

1977 were presentations of some part of the head, of which 8 were face presentations—about 1 in every 253 births.

42 were presentations of the breech, or some part of the inferior extremities—about 1 in every 48 births; of these 9 were twins.

6 were transverse presentations at full time—being 1 in every 337½ cases; they were all delivered by “turning.” Of these 1 was a twin, still-born. Two others were born still; with 1 the funis prolapsed; the other was the third transverse presentation the woman had had out of 14 children.

In 1 case the placenta was implanted entirely over the os uteri; the child was “turned,” and born living; the uterus contracted well, and the flooding ceased; the patient seemed to be going on very satisfactorily for 21 hours, when she was suddenly seized with a return of the hæmorrhage, without any assignable cause, and died in seven minutes.

6 were complicated with alarming hæmorrhage before the birth of the child; not the result of placental presentation—about 1 in every 334 cases. One of these was a breech case, premature; the others were at full time. One of the patients died three hours after the child was naturally expelled; there had been excessive hæmorrhage, which ceased on the membranes being ruptured; the child was born dead; she did not lose any blood after, but never rallied. One woman was delivered by “turning;” the child was saved; all the other children were expelled dead by uterine action; the hæmorrhage being restrained by evacuating the liquor amnii. With the exception just mentioned, all the women did well.

In 7 the placenta was retained within the uterus, either by atony or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—about 1 in every 282 cases; one of these was a twin case; one woman died on the 8th day after delivery from inflammation of the lungs; another on the 17th day, from an old pulmonary disease which had existed eight years.

8 were complicated with alarming hæmorrhage after the natural expulsion of the placenta—about one in every 250 cases. In one case both the child

and placenta were expelled before the arrival of the midwife. In another the patient was going on very well till the 9th day, when, after making some unusual exertion, she was seized with a copious flooding, and fainted. It soon ceased, and she did well. One woman died in five hours of internal hæmorrhage.

4 were delivered by craniotomy—about 1 in every 500 cases; two of these were face presentations; one a first child; in both the head was so wedged in the pelvis that neither the forceps nor vectis was of any avail. One woman was perfectly exhausted by starvation; the pelvis was rather distorted. She could not be restored, and died on the 6th day. In the other case the pelvis was narrowed at the brim; it was the woman's third child; both previous had been born living after very lingering labours. The membranes had broken 40 hours when I delivered her, the head was entirely above the pelvic brim, and there were tolerably sure indications of the child being dead.

7 were delivered by the forceps; one by the long, and 6 by the short instrument; about 1 in every 282 cases. Where the long forceps was applied it was the woman's fifth labour; she had once borne twins; her labours with that exception had been lingering; the membranes had broken 27 hours, the principal part of the head was above the pelvic brim, which was not more than three inches in diameter; neither ear could be felt; the face was to the right sacro-iliac symphysis. One blade was applied over the right brow, the other behind the left ear. The child was born living, and the woman did well. In two of the cases where the short forceps was used, the woman had had children before; in each there was a small pelvis, and a cicatrix in the vagina, the result of previous sloughing; in one the cicatrix was divided by a scalpel before the forceps was applied; in the other it gave way under the action of the instrument; both these children were born living; two other of the children were also born living; the other two dead. All the women recovered.

1 was complicated with a rupture of the uterus; the woman had had a family; there was not a small pelvis; the head presented; she died rapidly, before the district surgeon, who had

been sent for, could arrive. Dissection proved that the child and placenta had both passed into the abdominal cavity. Besides these cases one woman suffered a transverse rupture in the cervix uteri, under the expulsion of a blighted ovum about the size of a doubled fist. She believed herself near her full time, and had been the subject of hæmorrhage for a fortnight; as it increased, and she was in much pain, the district surgeon was sent for, who removed the ovum from the vagina. In doing so he detected a rent, and sent to me. I felt the ragged edges also distinctly; it appeared to extend almost across the whole of the neck; I could distinguish the posterior wall of the bladder most easily; but it appeared to me that the peritoneum was not implicated. The woman recovered without suffering much from inflammatory symptoms. I never met with such a case before, and I confess I do not comprehend how it could have occurred: the woman had had a family; the uterus had not exerted itself greatly, and the ovum could not have afforded much resistance in its passage; but both Mr. Burchell and myself were perfectly satisfied that there was a large laceration, and that it was above the os uteri.

11 women died either from puerperal causes, or within the puerperal month—one in every 182 cases; only 8, however, as a consequence of labour—being one in about every 250 cases; for one died of confirmed phthisis, another of pulmonary disease of long standing, which was characterized as “asthma,” and one of scarlet fever.

1953 children were born living.

72 children were born still—one in about every 28 births.

Of the Deaths,

3 were from the effects of hæmorrhage: one twenty-one hours after delivery under placental presentation; the flooding had ceased, and she appeared safe; it returned violently, however, and she died in seven minutes. One three hours after natural delivery under accidental hæmorrhage. One five hours after delivery of a dead child. There was no external flow, but the uterus relaxed and filled.

1 on the sixth day after delivery by craniotomy; the woman sank exhausted from previous starvation.

1 from ruptured uterus, suddenly, before any assistance could arrive.

1 from peritonitis, eleven days after delivery.

1 from pneumonia, eight days after delivery; there had been an adherent placenta.

1 from “asthma,” from which she had suffered for eight years, on the seventeenth day after delivery.

1 from pneumonia, a month after delivery.

1 from confirmed phthisis, a fortnight after labour at seven months.

1 from scarlet fever, three weeks after delivery; she caught it of her children, who were all ill with it, before she went into labour.

Of the still-born children,

21 were premature.

7 were putrid, at full time, or nearly so.

6 were breech presentations, at full time, or nearly so.

3 were transverse presentations at full time, or nearly so.

4 were delivered by craniotomy.

2 were delivered by the forceps.

1 was after the uterus had burst.

6 were under very lingering labour.

4 were after violent accidental hæmorrhage.

With 7 the funis prolapsed by the side of the head.

With 1 the funis prolapsed by the side of the breech.

1 was after the mother had suffered an accident.

9 were at full time, not putrid, nor delivered by art; there being no assignable cause for their not being born living.

ON CERTAIN POINTS

IN THE MECHANISM AND PHYSIOLOGY OF THE CIRCULATION OF THE BLOOD.

By GEORGE ROBINSON,

Fellow of the Royal Medical and Chirurgical Society, &c.

(For the *London Medical Gazette*.)

[Concluded from p. 493.]

I MAY, however, previously remark, that, by thus referring the active absorbing power to the streams of blood, we are at once furnished with a satis-

factory explanation of the fact, that the circulation through a part is necessary for the occurrence of an appreciable amount of absorption.

In answer to the first question, I may repeat the statement incidentally made when speaking of the conditions essential to absorption, viz. that this action is confined to the terminating portion of the capillaries and the small veins. In support of this opinion may be mentioned,—

1. The indirect evidence constituted by the facts and arguments adduced in the first part of this memoir, in order to shew that an effusion of certain portions of the blood is constantly occurring through the coats of the small arteries and contiguous portion of the capillaries; and if this conclusion be a correct one, it is evident that no *active* absorption can be proceeding in the same.

2. I have attempted to shew, by imitative experiments, that every circumstance connected with the arrangement, structure, and relations of the veins, is calculated to favour the absorbing power of the streams of blood by which they are traversed. Thus I found that, with a membranous tube and an ascending stream, absorption could only be obtained by copying, as closely as possible, *every* peculiarity observed in the veins of animals; and while engaged in devising an apparatus which should rudely represent some of the contrivances employed by nature in her most elaborate works, I could not resist the conviction that, if it were possible for man to construct an arborescent system of minute membranous tubes, similar to the veins of animals, the streams traversing which should possess the same physical properties, follow the same converging course, and be in every respect subjected to the same physical conditions as the blood contained within the veins, then the same physical result, viz. the rapid absorption of any external fluid, would most undoubtedly be obtained.

3. Fodera, who watched the process of absorption under the microscope*, observed the coloured substance to appear, first in the most minute venous radicles, and then in the larger veins.

I have before remarked, that the ab-

sorbing power of streams is *ceteris paribus* proportioned to their velocity; and, as connected with the point now under consideration, I may refer to the interesting fact, that natural philosophers, from reasoning upon the physical arrangement of the system of blood-vessels, long since concluded that the point where the blood flows with the greatest velocity is at the commencement of the veins*.

The next question, viz. as to the means by which the passage of fluids into the interior of the blood-vessels is accomplished, involves an examination of the nature of the absorbing power exercised by all rapid streams; and in the following brief explanation of this action, I have endeavoured to limit myself as closely as possible to the relation of such facts as appeared best calculated to render intelligible the process of vascular absorption in animals.

It is well known that a fluid in rapid motion does not press equally in all directions, its lateral being invariably less than its onward pressure; for if those forces were at all equal, every liquid jet, instead of contracting somewhat after escaping from an orifice, should represent more or less of the appearance of a rapidly diverging cone.

As before mentioned, it has also been proved by the experiments of Venturi and others, that when a rapid stream traverses a short conical tube, the whole surface of that stream possesses the power of drawing into the tube any stagnant fluid with which (by means of a lateral opening) the interior of that tube may communicate; and in repeating these experiments with a strong jet, I have found the same ascent and influx of the external stagnant fluid to occur, whether the communicating glass tube were fastened to the upper, or lower, or lateral, surface of the main pipe.

In explanation of this phenomenon, it may be stated, as a general principle, *that all bodies, while in a state of rapid motion, possess the power of carrying with them the contiguous particles of any surrounding stagnant fluid.* Thus a jet of liquid, or one of gas, or a rapidly revolving wheel, or any pro-

* Recherches Experimentales sur l'absorption et l'exhalation, par Michel Fodera, page 26. Paris, 1824.

* "L'endroit où il (le sang) doit se mouvoir avec le plus de rapidité c'est à l'origine des veines." (Musschenbroek, Essai de Physique, t. 1, p. 392. Leyden, 1739.)

jectile, will each speedily cause a current of the surrounding air to flow in the same direction.

I have even found that, on holding the orifice of a glass tube at a right angle to the surface of a strong jet of water, the ascent and discharge into the stream of the liquid into which the other end of the glass tube dipped took place with the same rapidity as when the jet traversed a rigid pipe*. Hence it appears that a stream can exercise an active absorbing power without necessarily entering any kind of pipe; for it is merely necessary to bring the orifice of the connecting tube in contact with any part of the surface of the stream, inasmuch as the absorbing power exists throughout the whole extent of the moving column. A strong blast of air, directed across the orifice of the tube, caused a similar ascent of the coloured liquid in the other arm.

Now if, instead of an open jet thus made to sweep across the orifices of a great number of tubes held at right angles to it, we suppose a similar current of liquid to flow along a vessel the walls of which are perforated by innumerable small apertures, it can then be readily understood that the stream, in crossing the orifices of all these minute lateral tubes, will exercise the same power of drawing through them any stagnant fluid with which they may communicate externally. In this point of view, the pores situated in the coats of the smaller blood-vessels may be regarded as so many minute short tubes, the internal orifices of which are directed nearly at right angles to the streams of blood, and the external orifices of which are in contact with the various substances absorbed.

The statement that all moving masses possess the power of inducing a corresponding movement of the fluid particles immediately surrounding them, being thus capable of direct proof, it now only remains to be shewn that the entrance of an external fluid into the interior of a tube traversed by a rapid stream depends upon a diminution in the amount of pressure acting on the internal surface of that tube.

The ascent of stagnant liquids observed in the experiments of Venturi

has very justly been referred to atmospheric pressure, or, in other words, to diminished pressure *within* the tube traversed by the stream; and that this is the true explanation of the phenomenon is proved by the following among other reasons.

1. To ensure the success of the experiment all the joinings of the apparatus must be perfectly air-tight; otherwise the ascent of the stagnant liquid will be very limited.

2. The same stream which drew up a column of water to the height of twenty inches, raised mercury to the height of one inch and a half only, which elevations bear to each other very nearly the same proportion as the specific gravities of these two liquids.

3. The following experiment, performed by Hauksbee, at the commencement of the last century, is interesting, not only for the clear light which it throws upon the present question, but also from its establishing for this country the credit of the first discovery of this particular property of currents.

A quantity of highly compressed air was made to pass through a pipe, which by means of two lateral branches communicated with the cisterns of as many barometers, one of which was placed at the distance of three feet from the main pipe.

"The result of which was, that this rapid current of air so lessened the pressure of the atmosphere upon the stagnant mercury in the cisterns of the respective barometers, that the mercury was made thereby to descend at least two inches. Nay, that barometer which was three feet distant from the aerial stream was equally affected as the nearer one." "And it is further observable, that as the force of the current of air diminished, so the weight of the atmosphere recovered its strength again, and forced the mercury in the barometers to a gradual ascent*." This experiment was undertaken with the view of discovering the cause of the descent of the mercury in barometers during a storm. And I may add, that the few remarks which the author makes upon the probable influence on the animal body of a diminished atmospheric pressure, are, so far as they

* A detailed account of this and some analogous experiments was contained in a paper lately read before the Royal Society.

* Physico-Mechanical Experiments, by E. Hauksbee, F.R.S. 2d Edition, London, 1708. pp. 114 and 115.

extend, very much in unison with the physiological principles advocated in this communication.

It is therefore evident, that the entrance of an external fluid into the interior of a porous tube traversed by a rapid stream, is a consequence of the pressure then acting on the internal surface of that tube being less than that of the surrounding medium.

When the tube is exposed to the air, and a quantity of this gaseous fluid is absorbed, the pressure of the atmosphere is evidently the sole cause of the phenomenon; but when liquids are absorbed, the weight of the external stagnant column co-operates with that of the atmosphere in effecting absorption.

In the animal body, this external pressure—the *immediate* cause of absorption—varies much in different parts, both as to its degree, and also as to the nature of the particular forces constituting it.

Thus, in the lungs, the weight of the atmosphere is the only force that can act on the exterior of those minute blood-vessels through which absorption is known to occur with extreme rapidity; whereas the whole contents of the abdomen are, in addition to being subjected to the action of the ordinary causes of external pressure, forcibly compressed by the diaphragm and abdominal muscles. By the contractions of the alimentary canal, the nutritious matters are, moreover, forced against the walls of the blood-vessels ramifying upon the intestinal coats.

This latter fact—viz., that in that particular part of the body where the absorption of food is effected, there exists throughout the animated creation an express contrivance for increasing the pressure acting on the exterior of the blood-vessels—does appear to me to constitute a very powerful argument in support of this view of the nature of the absorbing process. And when, in the treatment of disease, a more active absorption is desirable, experience has shown that there is no more effectual mode of accomplishing this object than by increasing the external pressure in the affected part. It is, of course, requisite that the external force applied should never exceed a moderate amount; otherwise the circulation through the part, and with it all absorption, would be totally arrested;

whereas a more gentle support not only facilitates absorption *directly*, by forcing the surrounding fluids into the interior of the blood-vessels, but, by diminishing the diameter of the latter, and thus increasing the velocity of the currents of blood, it also adds *indirectly* to their absorbing power.

I have made no mention of the manner in which absorption might be supposed to be effected by the lacteals and lymphatics because it appears to me very doubtful whether those vessels really possess any *active* absorbing power of their own. On the contrary, the information already possessed on the subject of absorption, the intimate connection shown to exist between the rapidity of the circulation of the blood and the activity of the absorbing process, the dependence of the latter on the former action, and the absence of any adequate mechanism in the so-called absorbent vessels, all tend to invest with probability the opinion—which was, I believe, first advanced by my friend Mr. Fenwick*—viz., that the substances contained in these vessels are derived from the adjacent blood-vessels by a process of effusion analogous to secretion.

It might to some appear improbable, that in a system of continuous tubes like the blood-vessels, through the walls of which, in the earlier part of their course, effusion has been shewn to occur, the opposite process of absorption should nevertheless be enabled to proceed throughout the rest of their extent. To meet this difficulty, I may briefly relate three experiments—one performed with a rigid, another with an elastic and yielding, and the third with a membranous tube—in order to shew that, when a stream encounters an obstacle in the middle portion of a tube, effusion necessarily occurs through any lateral openings situated behind the impediment, while absorption will, in accordance with the principle illustrated by one of the experiments to which I have referred, proceed with increased rapidity through the apertures placed on the other side of the obstacle, viz., nearer to the discharging orifice.

Exp. III.—A leaden pipe, a yard long, and half an inch in diameter—the central part of which had previously been much curved—was fastened

* MED. GAZ., July 21st, 1843—vol. xxxii. p. 605.

horizontally to a reservoir, and two small apertures were made on its upper surface at a short distance from either end of the curved portion of the tube. On passing a stream of water through it, the impediments, constituted by the existence of these lateral curves, caused a small jet to escape from the aperture placed behind the latter, while a rapid absorption of air, or of any other stagnant fluid with which it communicated, took place through the opening situated nearer to the discharging orifice of the pipe.

Exp. IV.—A piece of the aorta of a horse, eight inches in length, was fastened horizontally to the reservoir, and two bent glass tubes, one arm of which dipped into a coloured liquid, were inserted into two of its lateral branches situated at a distance of four inches from each other, all the other lateral openings being carefully closed. The central portion of the pipe was now grasped at a point equally distant from the insertion of both glass tubes, and its calibre there considerably diminished, so that the stream would in the first instance pass from the wide to the narrow portion of a conical tube, and subsequently from the narrow to the wide part of a similar tube. Under these circumstances a copious effusion occurred through the glass tube communicating with the first portion of the pipe, and an active absorption through that leading to its second division.

Exp. V.—The perforated membranous tube used with the apparatus described under Experiment 2, being held horizontally in the open air, and slightly pressed at one point, effusion occurred through the lateral apertures behind that point, while numerous globules of air entered those situated nearer to the escaping jet.

It will, I trust, now be considered as proved, that the active power employed in the animal body for the performance of absorption resides in the currents of blood which incessantly traverse the veins and terminating portion of the capillaries. This opinion, like that of Magendie, rests upon the fact of the permeability or porosity of the walls of the smaller blood-vessels; but it differs from his in withdrawing the substances placed in contact with those pores from the sole control of powers with which we are not well acquainted, and in substituting for the latter the more general

and intelligible cause of fluid motion; viz. unequal pressure.

I agree with Sir D. Barry in thinking that the relative vacuum formed within the thorax during the act of inspiration, greatly assists the process of absorption. But I contend that it does so *indirectly and mediately*; viz. by increasing the rapidity, and facilitating the passage of the streams of blood traversing the veins.

As giving a concise view of the general action of the causes producing effusion and absorption, it may be stated that effusion is promoted, 1st, *directly*, by whatever *increases* the amount of pressure acting on the *internal* surface of the blood-vessels; and 2dly, *indirectly*, by whatever *diminishes* the pressure acting on their *exterior*. While absorption is rendered more active, 1st, by whatever *directly increases* the amount of *external* pressure; and 2dly, by whatever *increases* the rapidity of the currents of blood, and thus *diminishes* the pressure acting on the *internal* surface of the absorbing blood-vessels.

PART III.

Being an attempt to inquire how far the entrance of certain gases into, and the discharge of others from, the interior of the blood-vessels may be accounted for on the general principles of effusion and absorption.

It now only remains to inquire how far the same views are applicable to the explanation of those functions in animals which consist in the extrication and discharge of certain gases from, and the absorption of others into, the mass of circulating blood. Here the doctrine of capillary attraction is confessed to be incapable of explaining the phenomena*: they are therefore generally referred to the mutual penetrability of gases.

That the extrication of carbonic acid in the lungs is materially facilitated by this property of diffusion, I can readily believe; but are we to suppose that this discharge of carbonic acid from the blood occurs equally in *every part of the pulmonary vessels*, and that the absorption of oxygen in like manner takes place with equal activity in the minute arteries and veins, and throughout the whole extent of the capillaries of the lung? There are many recorded

* Magendie, Journal, t. 1, p. 18.

observations which militate strongly against such a supposition. And as many of these phenomena are perfectly explicable by the general principles of effusion and absorption, I may, perhaps, be excused for now briefly noticing some of the more important of them. It was shewn by Lower, not long after the discovery of the circulation, that the change from venous to arterial blood takes place during the passage of the former fluid through the small vessels of the lungs. Subsequent experiments have proved that this change consists essentially in the discharge of carbonic acid from, and the absorption of oxygen into, the mass of blood. And as the blood circulating through the lungs does not present the bright red colour of arterial blood till it has entered the small pulmonary veins, this circumstance alone justifies the presumption that the absorption of oxygen by the blood is effected in this part of its course.

The property of mutual diffusion possessed by gases, is useful, not only as facilitating the discharge of carbonic acid gas through the lining membranes of the lung, but also from its enabling us to explain why that discharge is not general throughout the body, and why it only takes place on a free surface; where the external pressure is inconsiderable, and where the surrounding atmosphere presents a species of vacuum into which the imprisoned and compressed gases may freely expand. But it does not throw any light upon the means by which gases are *absorbed* into the blood. And I shall now mention some reasons for thinking that the absorption of gases is effected in the same manner as that of liquids, viz. by a preponderance of the pressure acting on the exterior of the absorbing blood-vessels.

1. That the absorption of oxygen in the lungs takes place in the terminating portion of the capillaries and the small pulmonary veins, is, to say the least, rendered highly probable by the above-mentioned observation of Lower.

2. The general absorbing power of the healthy lung is extremely active; so that any poisonous substance brought in contact with its lining membrane produces its effect upon the system almost instantaneously.

3. Atmospheric air, or any other gas injected into the cellular tissue of

the body is, if the quantity be moderate, speedily absorbed.

4. It is fully proved that streams of liquid possess the power of absorbing, through the lateral apertures of the containing tube, any gaseous fluids that may be in contact with the exterior of the latter. I have also found that this absorption will occur through an intervening layer of animal membrane.

Since, then, all other rapid streams, while traversing porous tubes, possess the power of absorbing any external contiguous gases, since that power is shewn to be possessed by the streams of blood passing through the systemic blood-vessels, and since the general absorbing power of the pulmonary blood-currents is known to be extremely active, it appears to me impossible to resist the conclusion, that the entrance of gases into the mass of blood circulating through the lungs takes place in the same part of the blood-vessels, and is effected in the same manner, as the absorption of liquids.

This view is moreover supported by some experiments by Leroy d'Etiolles, and related by him in Magendie's journal*. He found that on causing animals to breathe highly compressed air, and thus increasing the external pressure acting on the blood-vessels of the lung, the absorption of that air was so rapid, that the whole mass of blood not unfrequently became quite frothy.

And the whole of these considerations also tend to prove the correctness of the opinion in part entertained by Sir H. Davy†; viz, that the atmospheric air is, in the lungs, absorbed as such (for we know of no power by which the oxygen could be taken into the blood-vessels and the nitrogen rejected); that the oxygen of the absorbed air combines with certain portions of the blood during the systemic circulation, and that the residual nitrogen is, with the carbonic acid, discharged through the walls of the exhaling portion of the pulmonary vessels.

It is known that the opposite change from arterial to venous blood depends upon the presence of carbonic acid in the latter fluid; and it is generally believed that this change is effected in

* Journal de Physiologie, t. 8, pp. 106 and 109.

† Researches concerning the Nitrous Oxide. London, 1800. pp. 429, 447, 449, &c.

the systemic capillaries and minute veins, by the absorption of various products resulting from the decomposition of the tissues. Among other matters carbonic acid is of course copiously generated, and by its absorption the change of colour is produced. In like manner, when the main artery of a limb is tied, the blood which enters the trunk below the ligature, and which has necessarily passed through minute anastomosing branches, is immediately found to possess the colour of venous blood. Now this blood has evidently been placed under nearly the same physical conditions as the blood contained in the veins; for to arrive at the lower portion of the main artery, it must have traversed two systems of arborescent tubes; in the first of which the streams diverge, and in the second converge.

Those streams, therefore, which flow in the same course as the currents contained within the veins, exercise the same property of absorption; whence the change of colour resulting from the entrance into the blood of a quantity of carbonic acid.

It thus appears that while the absorbing blood-vessels of the lung take in atmospheric air, those distributed throughout the rest of the system receive carbonic acid; which, with that generated in the mass of blood itself, escapes from the exhalant vessels of the lungs.

Physiologists and natural philosophers have long supposed that many of the purposes served in the animal economy by the circulation of the blood are accomplished by the operation of ordinary hydro-dynamic principles.

In the preceding remarks I have endeavoured, through the medium of those principles, to establish an intimate connection between certain important functions in animals and the great discovery of Harvey, viz. the incessant motion of the blood. In the course of this attempt I may occasionally appear to have diverged somewhat from my more immediate subject; but these slight digressions, if they should be considered such, may perhaps be pardoned, inasmuch as they constitute an imperfection which must be common to all who seek for a solution of the mysteries of organic life in the simpler, and not less beautiful, laws of inanimate matter.

MR. ROSE ON CŒNURUS AND ACEPHALOCYSTS.

To the Editor of the Medical Gazette.

SIR,

In the *Periscope* of the last number of the *Medico-Chirurgical Review* (April, 1844) page 473, appears an article entitled "Researches on the Transmission of Hydatids by Contagion," by Professor Klenke, of Brunswick. The summary which the editor has given of the Professor's observations contains the following remark upon the polyccephalous hydatid, or cœnurus. "As far as we know at present, the only species whose habitat is very much restricted, is the polyccephalous entozoon, which has hitherto not been found in any other part except the brain." Having, several years since, met with a polyccephalous hydatid in a different locality, I beg to refer to my brief account of the circumstance in a paper on Hydatids, published in the *LONDON MEDICAL GAZETTE*, vol. xiii. p. 206. After having given a description of the cœnurus cerebialis as found in the sheep, I proceed to state, that "this is the only species of cœnurus noticed by authors, but I have met with another; it infests the rabbit, and I found it situated between the muscles of the loins; it is also met with in the neck and back. This hydatid grows rapidly, and multiplies prodigiously; and, being seated near the surface, it soon projects, and sometimes forms a tumor of considerable magnitude. When the warrener meets with a rabbit thus affected, he punctures the tumor, squeezes out the fluid, and sends the animal to market with its brethren. I possess a specimen of this species in a pregnant state: the earliest visible stage of gestation is a minute spot, more transparent than the surrounding coats of the parent; this enlarges till it projects from the parietes of the maternal vesicle; it continues to enlarge until it becomes a perfect hydatid, attached by a slender peduncle only; even whilst small, other young are seen sprouting from it, and so on in a series of three or four. My specimens exhibit them in every stage of growth—from a minute point to a vesicle the size of a hen's egg. As I can see no difference of structure between this hydatid and the last-mentioned (cœnurus cerebialis), I am unwilling

to consider it a different species; for surely a varying locality ought not to constitute a specific character."

A more recent dissection of a rabbit furnished me with the following observations:—The cyst enclosing the hydatids was situated in the cellular tissue uniting the common integuments to the fascia covering the lumbar and dorsal muscles; the fascia was the floor of the cyst; the cyst was formed of condensed cellular membrane; it was divided into three or four compartments communicating freely with each other; the cyst, for the more part, laid above the muscles, but at the fore part of the trunk it was covered by the *panniculus carnosus*, and had also extended under the *subscapularis* muscle, between the latter and the muscles covering the ribs. The largest compartment of the cyst contained two hydatid vesicles, each as large as a St. Michael's orange, besides numerous others attached to each other, and many unattached, from the size of a pin's head to the larger magnitude above mentioned. On the large vesicles young hydatids were forming, more particularly among the *vermiculi*; all projected externally, I saw no internal offspring attached or unattached. On reference to Rudolphi's work, "Entozoorum sive Vermium Intestinalium Historia Naturalis," Vol. II. Part 3, p. 301, I find that he describes but two entozoa as infesting the rabbit—*tenia pectinata*, and *cysticercus pisiformis*, the habitat of the latter being the peritoneum. The mammalia stated by the same author to be subject to the cœnurus, are the giraffe, African antelopes, sheep, and the ox; and in every instance the habitat of this parasite was the brain (op. cit. pages 302-3).

Now that I am on the subject of hydatids, I will embrace the opportunity of mentioning a very recent dissection of a monkey. The animal had long suffered from cough and dyspnoea, and at length died, in consequence of the impossibility of sufficiently expanding the lungs for vital purposes, the cavity of the chest being so extensively occupied by a colony of hydatids inhabiting the lungs. Upon the death of the animal it was sent to me for inspection, in compliance with my request. The examination of the cavities of the thorax and abdomen brought into view an extraordinary development of ace-

phalocysts. In the lungs I observed seven large cysts containing hydatids, the largest as big as a golden pippin; the liver also was occupied by several, and one large cyst lay upon the right kidney enveloped by the peritoneal coat of that viscus; a few were developed in various parts of the omentum and mesentery, and some were loose in the cavity of the peritoneum. I opened one peritoneal cyst, it contained several hydatids, varying in size from that of a pin's head to that of a filbert; the same cyst also contained what appeared to me to have been a larger vesicle (probably the parent vesicle), which had burst and fallen into folds.

Within the enclosing cyst, formed of either the pleura or peritoneum, I found in most instances from ten to twenty acephalocysts, of various magnitudes, some as large as a pullet's egg; in a few instances a solitary vesicle was met with occupying a cyst. The parasitic vesicles were invariably developed immediately beneath the pleural or peritoneal covering of the viscera, and did not appear to implicate or enter into the parenchymatous structure of either viscus, the liver and kidney being perfectly healthy, as also were the lungs, with the exception of a general emphysematous state; the laborious breathing of the animal having, without doubt, ruptured numerous air cells.

In elucidation of the structure of the acephalocysts, and confirmatory of what has been stated by others, I observed that the first visible effect of decomposition was a separation of the inner layer of the vesicle, closely studded with minute spherical bodies (*gemmæ* P): this layer fell into folds, and floated in the fluid of the vesicle. The fluid also contained an abundance of these bodies, which under a powerful microscope exhibited the forms of nucleated cells. Upon further decomposition the parietes of the vesicle could be separated into four laminæ at the least.

I take this opportunity of recording that in the course of my professional career I have witnessed three instances of the expulsion of parasitic hordes from the lungs and the liver of the human body, followed by the ultimate recovery of each patient. The first case occurred in 1828, in which the patient, a shepherd's wife, ex-

pectorated hundreds of acephalocysts, occasionally accompanied with hæmoptoe; she still lives, enjoying tolerable health; suffering chiefly from dyspnœa.

The second case was that of a tradesman's wife, labouring under chronic enlargement of the liver: in the summer of 1833 suppuration took place in that viscus, with adhesion to the abdominal parietes; late in July the abscess burst externally, and on August 12th my patient presented me with two hydatids which had passed from the opening; one had burst in its transit, but the other I was highly gratified to find uninjured, and a beautiful specimen of *echinococcus hominis*. Afterwards, more escaped with numerous acephalocysts; and about Christmas 1835 the sinus closed. No return of the disease took place; she regained tolerably good health, which she retains at the present time. In the third case, a farmer's wife experienced a circumscribed tumor on the right side of the abdomen, extending from the false ribs to the pelvis, and approaching nearly to the umbilicus; it was rather compressible, with but little tenderness. The patient had long been out of health, suffering chiefly from dyspepsia: at this time (February 1836) she was troubled with a cough. She called my attention to the tumor early in March, from which time it daily became softer in its centre, and by the 31st of the same month fluctuation was very distinct; there was also considerable symptomatic fever. About a month from this period the tumor began sensibly to diminish in size, and at the same time a copious purulent expectoration came on. In the first week of June, during a fit of coughing, she threw up an hydatid, unbroken, and about the size of a large pea; I was sitting by her bed-side, and saw it pass from her mouth; it fell upon the counterpane, from whence I took it; from this time, at intervals, she continued to cough up a considerable number, of various sizes, some as large as a nutmeg, but all broken. At the latter part of June and beginning of July she evacuated *per anum* large portions of dense semi-opaque membrane, of tender texture, resembling dead hydatid, accompanied with a considerable quantity of pus: by the 22d of July, nothing could be felt of the tumor with the exception of a slight thickening in the site. This patient slowly but pro-

gressively regained her strength, and is still in the enjoyment of excellent health. No explanation of the symptoms in the above case is necessary, as the causes of the highly interesting phenomena are sufficiently obvious.

I am, sir,

Your obedient servant,

C. B. ROSE,

Fellow of the Royal Med. and Chirurg.
Society of London, &c.

Swaffham,
June 8th, 1844.

INJECTION OF THE UTERUS

AS A MEANS OF EXPEDITING AND FACILITATING DELIVERY.

A FARMER in the neighbourhood of Edinburgh, son of a late eminent surgeon of that city, and well known to the editor of this journal, frequently had cows in great distress during their accouchment, and now and then perhaps, like other farmers, he lost a cow in the act of parturition. On one occasion, when a poor animal of considerable value had been suffering for a very long time, and there was every prospect of an unfavourable issue to the affair, as it seemed inevitable that the creature must die undelivered, the owner hurried into Edinburgh, distant about five miles, and took counsel with the eminent veterinary professor, Mr. Dick, as to the course to be pursued.

At the suggestion of that gentleman, he, with all the expedition possible, threw into the uterus from six to eight quarts of tepid water, the animal's hind quarters being previously elevated by a bundle of straw, so as to aid in preventing the return of the water. The instrument employed in the injection was the flexible tube (in fact, that used for the stomach pump), attached to Read's patent syringe, which was easily introduced over the shoulder of the foetus, the muzzle and fore-feet of which had been ascertained to be presenting at the commencement of the labour. The liquor amnii had completely escaped at a very early stage, and it was fully twenty-six hours afterwards before Professor Dick's excellent and ingenious advice was applied. But after the injection the calf was felt floating freely in the cavity of the womb. The animal, however, was so totally exhausted, that there still seemed no hope of the calf being expelled by the natural efforts.

Nevertheless, within five minutes after the injection of the water, a vigorous pain came on, and the patient was speedily and safely delivered of a live calf, and sustained no other ill consequences than a few days' weakness, the natural effect of her previous suffering.

Our friend mentioned this very ingenious plan to a neighbouring surgeon-accoucheur in large practice, who was so much struck with its simplicity and apparent safety, that he resolved to adopt it on the first favourable opportunity. An occasion soon presented itself, in a case where nothing but the long forceps could have effected the delivery of the sufferer; and shortly afterwards in a second instance, where turning and delivery by the feet would have been indispensable to save the patient's life.

In both cases the injection of about a quart of tepid water was attended with complete success; the patients were both delivered of living children by the natural efforts, without any unfavourable symptoms ensuing.

We have gathered these particulars from the owner of the cow, the gentleman who, with his own hands, made practical application of Professor Dick's valuable suggestion, believing that the procedure indicated is new, free from danger in itself, and likely in many cases to obviate the necessity for more formidable and painful operations.

DR. BUCHANAN ON FIBRINE AND ITS TRANSFORMATIONS.

On the fibrine contained in the animal fluids, the mode in which it coagulates, and the transformations which it undergoes. By ANDREW BUCHANAN, M.D., Professor of the Institutes of Medicine, University of Glasgow, pp. 11. (The Proceedings of the Philosophical Society of Glasgow, No. 7.)

THE most novel part of this paper is the announcement that the fibrine existing in the blood and other animal fluids, does not, as is generally supposed, exist in them in a state of solution, "but exists while yet within the body, already solidified and organized in the form of granules and vesicles; and that the process of coagulation consists,

simply, in the aggregation of these minute granules into a mass visible to the naked eye." This view of the matter seems to be very nearly allied to that long since promulgated by Sir Everard Home, and more recently by M. Milne Edwards.

Dr. Buchanan believes that "the solid and liquid portions, of which the circulating blood is seen to consist under the microscope, is the very same as the solid and liquid portions into which the blood, after being drawn, spontaneously separates; that the whole coagulum, or part which affects the solid form after being drawn, existed previously within the blood-vessels in the solid form; that during the coagulation of the blood there is no mysterious precipitation of a solid previously held in solution, but that the process of coagulation consists simply here, as in the cases already mentioned, in the aggregation of granules and globules previously existing diffused through the serous liquid, but not cohering; and that the only peculiarity in the coagulation of the blood consists in this, that some of the solid corpuscles, by the aggregation of which the coagulum is formed, are red, while others are transparent, and that the latter possess a much higher cohesive power than the former. It follows, if these opinions be correct, that the term "*liquor sanguinis*" should be banished from physiology, as conveying a whole series of erroneous ideas as to the constitution of the blood.

It has been shewn, by the researches of Magendie, Gulliver, and Addison, that a clot of fibrine is constituted of a network of filaments or fibrils, besides the corpuscles; and these fibrils, as figured by Gulliver (App. to Gerber's Anatomy, plate xxviii.; Lond. and Edin. Phil. Mag. for August and October 1842) and Barry (Phil. Trans. Part 1, 1842), are of extreme minuteness, and have no appearance of being formed by an approximation of corpuscles visible by the microscope in fluid blood. Besides, in Mr. Gulliver's figures, the accuracy of which Dr. Barry bears testimony to, the fibrils seem to constitute the mass of a clot of fibrine; so that it seems hardly possible that they could have been formed by the aggregation of fibrinous globules and granules previously existing in the fluid blood, in which simple process Dr. Buchanan

regards coagulation to consist. However, the question is an interesting one, deserving of further inquiry, which may be aided by a reference to Dr. Buchanan's paper, in which many more observations and arguments are recorded than it would now be convenient to extract.

The theory of Schwann, that reticular tissues are formed by the division of vesicles elongated into filaments, Dr. Buchanan dissents from, as he believes that the reticular form "depends on the arrangement of the vesicles in relation to each other, which, whether they retain their vesicular shape, or become filamentous, always affect a reticular arrangement."

The inadequacy of the cell theory to account for the fibrillation of fibrine has not escaped the observation of former writers: thus, Mr. Gulliver (Lond. and Edin. Phil. Magazine for October 1842) asks, "how is the origin of the fibrils which I have depicted in so many varieties of fibrine to be reconciled with the doctrine of Dr. Schwann? And what is the proof that these fibrils are not the primordial fibres of animal textures? I could never see any satisfactory evidence that the fibrils of fibrine are changed cells; and indeed, in many cases, the fibrils are formed so quickly after coagulation, that their production, according to the views of the eminent physiologist just quoted, would hardly seem possible. Nor have I been able to see that these fibrils arise from the interior of blood-discs, like certain fibres delineated in the last interesting researches of Dr. Barry."

On the subject of pus, Dr. Buchanan believes that it "is never formed, as many maintain, in inflamed vessels, and secreted from them," but that the effused serum is gradually converted into pus. This is in accordance with the observation of Autenreith (Diss. de Pyogenia, 114), who states that he has observed pus globules to be formed between layers of talc, in the watery liquid obtained from a wound, and subjected to the atmosphere of that wound, while he could see no such globules produced in the same liquid completely removed from the body.

Dr. Buchanan thinks that, in ordinary circumstances, it is probable that no fibrinous corpuscles originate in the sanguiferous system; which statement may be compared with that at the head of this article. The observation made

many years ago by Weber, is familiar to every microscopical observer, that colourless globules may be seen in great numbers in the veins of frogs; and the colourless corpuscles of the blood have been known since the time of Hewson. The term "fibrinous globules," however, is a very objectionable one, because it has been applied by M. Mandl to the globules of fibrine, pus, mucus, &c., while by other writers it is used in a more restricted sense; besides, it has never been clearly proved that the majority of the primary cells of morbid fluids are anything else than concreted fibrine. The cell germ, indeed—that molecule—may be fatty, according to Mr. Gulliver's observations in the Edinburgh Medical and Surgical Journal, No. 156. The size of the globules of laudable pus Dr. Buchanan states to be little inferior to that of the blood-globules, or of those of fibrine, which we mention merely to add that it is well known that pus globules are larger than those of blood.

NOTES OF A MESMERIC EXHIBITION.

(For the London Medical Gazette.)

[We have the following memoranda and observations from a gentleman who sends us his name, and in whose good faith and accuracy we have every confidence.—ED. GAZ.]

The exhibition to which the following memoranda refer, took place at a small concert-room in Mortimer Street, on Thursday, 11th July, 1844, from half-past twelve to two P.M. There were from thirty to forty persons present. The performer (Alexis) was thrown into a state of so-called somnambulism, by his friend, M. Marsillet, merely looking steadfastly at him while seated in a chair. With the exception of the first experiment, during which Alexis seemed to be asleep, all the others were performed while he seemed to a common observer, to be awake, with his eyes (when not bandaged) partially open. He appeared to see, hear, and know what was going on about him, just as any of the spectators. The only peculiarity that struck me was, that the eyelids were only partially open and occasionally quivering.

The following notes were written *immediately* after the meeting. If there be any inaccuracies in them, they certainly do not regard matters of any importance.

1. The left arm was extended in a state of rigidity, not opposing *very* great resistance to downward pressure. The pulse smaller in the rigid arm.—Any one could do this.

2. The legs extended in the same way. A gentleman *partially* stood on them, but not entirely.—Any one could do this with practice.*

3. Playing at *carté* with the eyes bandaged. He seemed to play readily and well, winning the game. He also told the cards at times in the partner's hand; but he also repeatedly failed, and made glaring mistakes in his guesses.

The whole of this experiment is vitiated by the doubt as to whether he could see under the bandage. From carefully and most closely watching him, I am of opinion that he saw or might see from under the bandage. I particularly remarked that while the bandages were being placed, he repeatedly touched and shifted them; and before they were removed, I observed most distinctly that he pressed a knuckle forcibly over the bandage into the hollow of each eye, *as if to close the leather that might have been removed*. I also observed that when examining some body presented to him, before the bandages were removed, he placed the body *to one side of him*, exactly as a person would do who was trying to see through a difficult passage.

At any rate, the evident (to me) *possibility* of sight being exercised in the ordinary way, totally vitiates this card-playing as an experiment.

4. The next experiment, after the bandages were removed, was reading in a book *through* a certain number of pages, *i. e.* telling *what words* (two or three) would be found opposite a certain point indicated on the open page, some pages farther on. The experiment was performed on a French book produced

from the pocket of a gentleman present, and was repeated three, four, or five times. Being close to Alexis the whole time, and watching him most carefully, and all his proceedings, I am bound to declare that the result was altogether inconclusive as to his possessing the power pretended.

a. In the first place, in no instance were the words named by him exactly under the point indicated on the open page. He hunted over many pages, and was satisfied (as were many of the spectators), if he found the word named *anywhere*, in any part of the page!

b. Secondly, I distinctly observed, in *every case*, that *before* naming the word or words, he turned over the leaves (apparently carelessly and heedlessly, but with his eyes never removed from them) in such a manner, that it was the easiest thing in the world for a person of ordinary sight to see *sideways* into the pages, and thus to catch words. This fact, coupled with the other just stated (a), utterly vitiates this experiment. It is also obvious that *only the first* of the experiments *could* be valid, as in searching for the *first words* he had the opportunity of fixing in his mind as many words as he pleased for the subsequent trials. And I observed that he would only look at those *parts* of the book which he had turned over.

5. The next set of experiments referred to his power of reading words wrapped up in paper, boxes, &c. and of generally indicating the contents of certain bodies presented to him.

The following were some of the experiments and the results:—

a. A gentleman (I believe Colonel Gurwood) presented to him something very loosely wrapped in paper. He felt it, and said it was a box (*boite*). He then himself removed the paper, and laid the apparent box (a small octagonal body with gilt top,) down on the table. He was then asked what it contained: he said, some characters in writing. While he was saying this (or previously, I don't now recollect which) he had *perfect opportunity*, as the object lay before him and was touched by him, and was constantly looked by him,—I say he had a perfect opportunity of *opening the book* (for such it was), so that he *might* see the characters within it. I cannot say positively that he *did* open it, but any body, not a juggler,

* "The influence of habitual exercise in strengthening any particular set of muscles is remarkably illustrated in the Vaida. I saw one, a young man of a diminutive and spare form, with slender arms and shoulders, use with the greatest ease a bow he had been accustomed to, which one of the strongest of our soldiers could hardly bend." Dr. Davy, *Researches*, Vol. I. p. 178.—*Ed. Gaz.*]

might have done so unobserved. He then announced that it was some writing in characters he did not understand. The book proved to be a copy of the Koran in Arabic. This experiment was clearly a failure, first, because *while covered* he declared the *book* to be a *box*, and second, when the paper was removed, there was—to say the least—no *impossibility* of seeing the contents in the natural way.

b. A slip of folded paper was given him. He examined it most closely, putting it to his chest, mouth, &c. and seemed to me cautiously looking for an opportunity of unfolding it, as he turned it over and over, and partially opened it, more than once. My eye was, however, so constantly fixed on his proceedings, that he could not open it unseen, and he did not open it. After an infinite deal of manœuvring, and asking many questions of the lad who gave it him, as if desirous of obtaining some help from his answers, he resigned it, and fairly said he could *not* read.

c. Another paper (it might be the same) he proceeded with in the same way, now often stating, inquiringly, the number of letters (which constantly varied, he sometimes saying six, eight, four, and so on). At last he said it was very difficult, *because it was folded on itself* (plié sur elle-même). He returned it to the lady that it might be unfolded. I went and saw it opened by the lady; *it was not in the least folded*. It was a boldly written word, either "*Londres*" or "*Angleterre*," I forget which.

d. One of these packets while manipulating (I now recollect it was the one I saw opened by the lady) he pricked through with a pin, saying "*he pricked the dot of the i*," and then "*the i itself*." When opened the word contained no *i*!

e. A lady (evidently a strong believer, and very friendly to Alexis) put herself in *rapport* with him, and produced a large box, like an over-grown card-case, or a case for holding a small prayer-book, (opening like a card-case in the middle). He took it in his hands and felt it, and turned it about. He was asked what it contained; he said, after a brief pause, something *gilded* (doré), and then said, a watch (montre), and added, that "*what was curious, the glass was broken*." The lady was surprised at this, and said it

was *not* broken when she gave it him. On opening the box by drawing off the top, sure enough there was a watch on one side, *with the glass next the outside*, and the glass was broken! Nothing could be clearer than that he *might* have broken the glass through the yielding case, or felt the broken glass, or heard or felt the watch *tick*, and thus come at once to know that it was a watch, and a watch with a broken glass! I believe this was the fact, but, at any rate, it must be admitted that such a clear-seeing as this *might* have been accomplished by any body, and therefore the experiment goes for nothing.

f. I had taken half a dozen boxes, and folded papers and sealed envelopes, each containing a French word, so wrapped up as that it was *impossible* to see into them with ordinary eyes. These lay on the table all the time, and I had repeatedly pressed on M. Marsillet to let him try one of them. But some excuse was always made. Meantime, a gentleman came forward with his two hands closed, and requested to be informed what they contained. Alexis took the hands, turned them round, and *I saw him distinctly separate them a little*, so that he *might* have seen what they contained, at least the *colour* of it. He first said, it is a *small thing*. The gentleman said, of course, or it could not be contained within the hands. Alexis then said, it is *reddish* or *darkish* colour, "*and, if broken (cassé), white inside*." After a long time, and trying very hard by leading questions, to find out something about it, he said it contained *writing* or *printing* (I forget which), said there was a large word with five letters in the centre, and some *arrangement of lines* which I now forget. After a long time, the hands were opened, and were found to contain a small morocco pocket-book, which was certainly reddish outside, and had some white paper and some printed or engraved cards inside. At this time I forget what was on the cards, but I am certain that the "*chief*" word of five letters was *not* there, and the lines were *not* arranged as Alexis had said. This experiment I regard as also a failure in every respect, except that there was something *white* inside. The red colour outside might have been seen; the *white* was *POSSIBLY* a guess; at any rate, the other mistakes committed are sufficient to neutralize this small suc-

cess, to say the least of it. I therefore maintain that this experiment *proves* nothing.

g. At length, after many attempts, I succeeded in getting a lady (a friend of Alexis, and favoured by him) to take one of my *boxes*, and put him to the test in my own way. She was put "en rapport" with him, but he would not attempt to read the word written within upon finding that *she* did not know what it was. She then went to one side of the room to examine the word, and I just arrived near her in time to see her take from the box the word, and look at it, *surrounded by many of the company. This was done openly*, and though I at once felt that this circumstance was sufficient to vitiate the experiment, as it was *quite possible*, and, indeed, *extremely probable*, that some of Alexis's *friends* might see it wholly or partially, and make him acquainted with it. However, I begged the lady to allow me to replace the word in such a manner that it could not easily be seen, even if the top of the box (a small paper wafer-box) were removed. Well, she returned to Alexis, and gave him the box. He looked at it long, and at last said inquisitively, "un mot de *cing* lettres!" then seven, then eight, and at last *five* again, adding, "I am now sure it is five." I begged her not to tell, and partly succeeded, though it was obvious she was desirous of *helping* him all she could. At last, he said the word ends with the letters *ion*, and tried hard to get the lady to help him out with the rest. If I had not constantly interfered, I saw clearly that he would have bothered or bamboozled her out of them. He then wrote on a paper *ion*, then tried several prefixes to suit, and at last seemed to settle on *motion*, or some word like this, but one certainly ending in *tion*. Two o'clock having now arrived, I was obliged to depart before the box was opened, but I was thoroughly satisfied that some one of his *friends* had had a glimpse of my word (it was in *large print*), and had told this to him. It was, however, a word not of five, or six, or eight letters, but one of *ten*, viz. "*Discussion*."

The conduct of Alexis throughout was altogether that of a man who was playing a deceptive part, and looking in all directions for help in his efforts to succeed in what was given him to

do. In all his attempts to read the words enclosed in envelopes, he invariably made, in the first place, inquiring guesses as to the word being in writing or print, and especially as to the number of letters; and he and his friends made unconcealed attempts to wheedle the party who gave the word, into conceding something so as to help him in solving the problem. "It is a word of five letters—eh?" "Is it a word of six?—No—it is—eh!" and so on.

Now it is certainly strange that if a man had the power of seeing the word through its covers, he should need such aid, or that such aid could be of any use to him. How can the knowledge of the *number* of letters in a word, or of the two or three first or last letters in a word, help a man to *see* the remainder? Of course, however, it may help him to *guess* them.

When he took the folded papers in his hands, I observed that in his manipulations—placing it to his stomach, &c.—he was frequently seen by me to unfold the edge slightly, just as if he *wished* to unfold the paper completely; and I observed also that he frequently shaded his face with his hand (*as if meditating*) in such wise *as would have enabled him to unfold such papers unperceived by persons at a small distance from him*, although my close watching rendered this impossible in the present case. I regard this as important, as it indicates how deceit may have been practised in other cases, and how apparent success may have been achieved.

It was also evident, throughout the exhibition, that Alexis had *several friends* (I do not call them *confederates*)—but they afforded, in their conduct, the strongest grounds for suspicion that they were such—who took an active part in trying to help him in his difficulties. Among other manœuvres, repeated attempts were made to get the spectators (and myself especially) removed from the table, under the plea that ladies could not see. A Frenchwoman—evidently one of the party—wished me to give one of my *boxes* to her, begging me at the same time to leave the room, as my presence as an unbeliever was hostile to the powers of Alexis, and that *then* she would get him to read the word it contained. Of course, had I complied, there was nothing

to prevent her from opening the box and naming the word to the performer. These, and other things of the same complexion, are not merely suspicious, but shew that, whatever the results might be, they could not be established on, or derived from, pure unquestionable evidence.

From the whole of the exhibition the following conclusions must be admitted:—

1. That the whole affair bore the complexion of trickery, or, at all events, that it wanted entirely the precision requisite in scientific inquiries.

2. That the total amount of positive failures and positive blunders greatly exceeded that of performances having even a colour or slight degree of success.

3. That the failures occurred in cases where the circumstances were such as to exclude collusion and the exercise of ordinary vision.

4. That all the instances of success occurred where circumstances allowed of collusion or ordinary vision.

5. That in all of the cases of success such collusion or vision was either proved or rendered extremely probable.

6. That there was not one single unequivocal example of what is called *clair-voyance*.

7. That, consequently, this exhibition not only affords not one tittle of evidence in favour of the existence of this faculty in the man Alexis, but presents extremely strong grounds for believing that the pretended power in him is feigned, and that he is consequently an impostor.

From what I witnessed at this exhibition, and at another where it was pretended that the so-called somnambulist exhibited the faculty of having the phrenological organs excited individually by mesmerism, I am much more satisfied than I used to be in regard to the probable causes of the extensive belief in the wonders of mesmerism. On both these occasions it was clear that many of the spectators were either totally unacquainted with the laws of evidence, or that their enthusiastic temperament, or previous convictions or prejudices, rendered them, for the time, incapable of appreciating, or of being guided by, such laws. They admitted, as positive facts, what appeared to calm unprejudiced observers, not only not facts, but

the merest assumptions, unsupported by a tittle of the kind of evidence required in scientific investigations. It was also evident that there was, among such persons, an endeavour to *help* the exhibitor to get at the results proposed, and an eagerness to believe every thing without question, and with a proneness of faith unjustifiable, and therefore never admitted, in inquiries of a scientific character. A further source of fallacy existed in the circumstances in which the great majority of the spectators were placed, viz. the utter impossibility, owing to their distance from the scene of action, of their seeing *exactly* what took place, so as to enable them to guard against the possibility of mistakes, misstatements, or collusion. These circumstances, taken in combination with the natural tendency of the human mind to believe rather than to be sceptical, and with the proneness of mankind in general to recollect successful wonders (especially in the way of guessing, divining, or prophesying) rather than failures, may, as I have said, help to explain the wide-spread belief in mesmerism, even if mesmerism should be false.

In concluding these hurried notes, I think it right to state that, even now, I only avow myself a sceptical doubter—not an utter disbeliever—as to mesmerism. I am still open to conviction when such evidence of its truth is afforded me as is deemed necessary in any other scientific inquiries. The things I have myself seen most assuredly increase very materially the doubts I before entertained; still I do not regard them as sufficient to prove the utter falseness of mesmerism: they prove nothing more than their utter insufficiency to prove its truth. Even the positive proof of trickery and collusion on the part of its professors, however, would afford no sound reason for declaring it to be false. Like medicine, or any other branch of natural science, it may be true although it be professed and practised by charlatans, cheats, and rogues. Give me the same kind of proofs of *clair-voyance* that I have of other scientific truths, and I will believe it.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Miscellaneous Contributions to Pathology and Therapeutics: on Rickets, Hydrocephalus, Impotence and Sterility, Pulmonary Apoplexy, and Hæmoptysis. By JAMES RICHARD SMYTH, M.D. Pp. 341.

THIS book is one of the class which is directly opposed to that in which systematic productions, monographies, and prize essays, naturally range themselves. In point of abstract utility these are unquestionably the most useful books. Besides making us partakers—which they may or may not do—of the writer's own opinions, they give us all the information extant upon the particular subject of which they treat. Systematic works, however, are generally very dull books to read; they are in fact unreadable. It would seem that no mere man had the power of sitting down to chronicle events in which he was no actor, and giving an account of views and opinions which are none of his own, with the same amount of interest felt, of interest communicated, as where he has himself been engaged personally and mentally; in order to interest, it is absolutely necessary to be able to say with the pious *Æneas*, *quorum pars magna fui*. The text must be of the preacher's own choosing before he can make a good sermon; one propounded to him will scarcely strike him at the moment, will hardly chime in with the prevailing mood of his mind; and then he finds that he can fashion it in no wise. It is even the same with books; unless the subject be of the writer's own choosing, and have burnt itself in upon his mind by long cogitation, he will never deal with the matter in a way that will carry the reader along with him. All the most interesting and entertaining books we possess have been produced under these conditions. But then, these books are often very far from being really good or useful books. They are frequently dedicated to the development of a mere crotchet, a whim, a fancy, to some one-sided view, to something that is merely personal to the writer, to something, it may be, that is important and true, to some-

thing, it may be, that is really insignificant, and it may be to something that is positively false. Their object is less to inform or instruct than to make the author himself, right or wrong, prevail. It is by their sincerity and earnestness that the writers of such books bear us along with them pleasantly, unhesitatingly; it is often only on coming to the end that we find we have been faring sumptuously—in a dream, that we find the pleasant drink we had been sipping was but froth, and that in the words of the poet—

Des Wissens Durst bleibt ungestillt
The thirst for knowledge still remains unquenched.

These observations we make altogether irrespective of the book whose title prefaces them. The book is an interesting book, and we think an useful one. It is written from various texts, obviously not selected for the author, but selected by him, and that because each several subject had met him in the world and craved his attentive consideration. The work is the record of the writer's views and experience in regard to the several important matters of which it treats.

Dr. Smyth's work consists of a collection of essays on rickets, on chronic hydrocephalus, on impotence and sterility, on pulmonary apoplexy and hæmoptysis, on rheumatic pericarditis and pleuritis, and on false aneurism.

Our author's views of rickets lead him to defective action of the chylopoietic viscera, and particularly of the liver, as its grand cause; he finds an enlarged state of this important organ in every case of the disease, and is "firmly of opinion that the practitioner who will view the infantile affection, now under consideration, (rickets) as one simply of hepatic disease, with more or less aggravated derangement of all the digestive functions, and apply his remedies judiciously in accordance with this view, will be most likely to benefit his patient" (p. 20).

We heartily wish that medical writers would come to some understanding in regard to the employment of the noun *scrofula*, and the adjective *scrofulous*. Dr. Smyth allows to both a great latitude of signification, when he says that he "considers the malady of rickets, as regards the softness of the muscles and bones, as nothing else than a scrofulous affection of these parts"

p. 21. This view of course would not satisfy those who would restrict the epithet scrofulous to cases in which there was a distinct deposition of tuberculous matter—an event known not to happen in rickets.

Having regulated the secretion of the liver, and the action of the bowels, by the ordinary alteratives, and gentle or more energetic aperients, Dr. Smyth's grand remedy in rickets is wholesome animal food, in fair, not in large quantity; and when to these we have added country air, and cold bathing, we should say that the treatment of rickets was exhausted.

We are "nothing if not critical," and Dr. Smyth will forgive us if we venture to suggest that the "unsettled opinion" which, at p. 61, he says he has, "that the motion of the blood in the child is slower than in the adult," is almost certainly erroneous. Further, we would have our friend in future to avoid the crowds of expletives which we encounter here and there; as where he speaks (p. 63) of the "*delicate and interesting* young ladies as *constituting the beauty, life, and joy, and attractive, captivating ornament and charm of society.*" This makes feeble writing of what would otherwise run smoothly yet forcibly enough.

The next essays are on chronic hydrocephalus, in which Dr. Smyth appears to have been the first in this country to observe a certain "auscultic phenomenon connected with the circulation in the brain, and consisting of an abrupt, rushing, arrested sound, in character between a bruit de soufflet and a bruit de rape; and which he describes under the title of *cerebral murmur*. It would appear that this murmur might occasionally serve as a diagnostic sign of some value. Dr. Smyth gives the particulars of a case of chronic hydrocephalus which he treated by tapping, but unsuccessfully.

The delicate subject of impotence and sterility appears to be treated with great propriety in the 7th, 8th, 9th, 10th, and 11th essays; in fact, it forms a very considerable proportion of the whole volume. There can be no question of the importance of the matter. Its delicate nature has probably kept it in arrear of other subjects of medical science. Dr. Smyth expresses his surprise at the little that is worthy of notice upon it which is to be found

in the writings of standard authors upon mental and other diseases.

Our limits do not allow us to follow our author either into this or the remaining subjects of his volume; but we beg to recommend it heartily to our readers, for the good taste and the good sense it displays.

MEDICAL GAZETTE.

Friday, July 19, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

MESMERISM.

IN a late number of our Parisian contemporary, the *Gazette des Hôpitaux*, amidst much that is extremely clever, as every thing is which flows from the pen of M. Raimond, we read these words:—

"It is long since we have heard any thing of magnetism. Can it be that all the high priests and priestesses of the worship are fallen into the magnetic sleep? With the exception of MM. Thilorier and Lafontaine, who have at length discovered the third imponderable fluid, so long and vainly sought after by others, and have proved its existence by making passes at the galvanometer, nothing new has reached me—nothing in regard to the Prudentias, the Virginias, the Colettas, and the rest of that elegant cohort of pretty little sleepers, which I so much love to look upon."

Seeing the magnetic tempest that rages around us in London at this time, we cannot but consider our Parisian friends lucky in their enjoyment of the calm. Far from hearing nothing of mesmerism in London, we seem to hear of nothing else; and what makes the interruption the less endurable now, is, that the business is altogether without its ordinary attractions. Neither have we the usual "*cohorte grecieuse et mignionne de charmantes dormeuses.*" to which M. Raimond alludes, nor

even any individual member of the choir, neither Prudence, Virginia, nor Coletta — instead of "Mistress Anne Page," we have "a great lubberly boy!"

We think the fraternity of magnetizers seriously in error here; they ought not to have passed "the sex." We had large faith in magnetism before we heard of Alexis, in comparison with what we have in it now that we have information as to his powers: the ladies bore off the bell all to nothing; they were as ductile clay in the potter's hand; the male lump of matter is at best but a kind of bird-lime—soft enough, indeed, but it sticks to the fingers, and there is no fashioning it, or keeping it in decent shape. But for the propping up of the priestesses of the faith, as M. Raimond calls them, Alexis would sink together like a mere jelly: the women are his great friends; and whilst they save him from the importunities of those of his own sex who would question him somewhat strictly, and who insist on looking after his manœuvres rather closely, they are eager to help him in his guesses. "There is an *a* in the word?" says the youth. The unsympathising male sex, who perceive that if Alexis could read with his stomach, as he pretends that he can, he would require to ask no questions, are all brutally silent; they will not say whether there is an *a* in the word or not; but the tender heart of a female friend cannot resist the insinuating query, and it confesses that there is an *a* in the word. "And an *i*?" continues the gentleman. *Conticuere omnes*—all are silent; but by and by it is wrung from another sympathising she soul that there is an *i* in it; and then, having immediately before been asked to read the word "Rouen," which he could not do, the prophet is delivered, and with the final throe gives utterance to the word "Paris," that word having an *a* and an *i* in it.—And

this satisfies the believers in magnetism, and somnambulism, and second-sight! If it does, they may be assured that it also satisfies the scoffers at their system.

For our own part, and quite seriously, we had been very much at a loss what to think of some of the phenomena of mesmerism up to this time. We saw the matter up to a certain point as fairly within our province of naturalist. When by certain manipulations we saw the external senses of a delicate woman whelmed in forgetfulness, the phenomenon met us as curious, and worthy of consideration, as all that pertains to natural phenomena is; but when we found a system of divination and of prophecy connected with the peculiar state which we were inclined to regard as having been actually induced, we began to be suspicious in regard to the primary phenomenon itself; for we felt quite sure that the disciples of Mesmer had now got beyond nature, and that, save on the wings of faith, we could not follow them.

The somnolence that is the effect of sustained attention to a trivial or monotonous topic we admit:—let any man lay himself down, who has not taken two cups of strong tea or coffee, and fix his eye on some point in the tester of his bed, or concentrate his attention on the cone of breath that issues at each expiration from his mouth, and in five minutes he will be asleep. Formerly the mesmeric state was only to be induced by passes; then it could be brought on by the fixed gaze of another; now it can be secured by the party fixing his own gaze upon some point above or below the plane of easy vision. Any thing like a peculiar influence—a magnetic fluid—transmitted from one human being to another, is therefore given up; the mesmeric state is induced without the passes, and without the gaze, of any

mesmerist. This being so, what becomes of the maintained necessity of one who would ask a question of the party mesmerized being first put in relation with the mesmerizer?—But we feel that we cannot properly pursue this subject farther here.

There are two orders of spirits in the world, one naturally inclined, another naturally indisposed, to mysticism and to belief; and we see that the general intellect is altogether independent of the mental constitution in this respect. Sir Matthew Hale believed in witchcraft, and Samuel Johnson believed in ghosts. The world has always held some kind of superstition or mysticism in respect. Judicial astrology served it for ages; mesmerism is in the ascendant at present. Judicial astrology has gone out of fashion; mesmerism has usurped its place; firmly believed in by one party of very respectable, very intelligent men, it is utterly scouted by another party of equally respectable, equally intelligent persons. These two parties should agree to differ on the subject of mesmerism. The believers ought to cease seeking to make proselytes among the incredulous; the unbelievers ought to give over endeavouring to shake the faith of the credulous.

In fact, the *ultimate phenomena* of mesmerism, if we may be allowed the expression in reference to clairvoyance or second-sight, are plainly beyond the domain of physiology: they are not functional manifestations of any organic part. Alexis, if he be anything more than a very ordinary mortal, must be a diviner, a prophet; and this, in fact, is what is claimed for him by his friends. As naturalists we stand upon such simple axioms as these: there is no effect without a cause; there is no function without an instrument; there is no organ that is not necessary to its office, &c. The first postulate of mes-

merism is that we give up these axioms; that we admit effects without causes, functions without instruments, instruments as needless to their special offices, &c. This we cannot do. Were we fitted by our mental constitution to entertain the mysterious system of mesmerism, we should accept Alexis as a prophet, and of course view him with the same reverence as the ancients did their sybils and pythonesses, their interpreters of futurity. There is one great difficulty that meets us at the outset, however, and prevents us doing anything of the kind; it is this: that since Christianity was given to man for his guidance, the oracles have been dumb.

We conclude by quoting a few lines from the heathen poet Horace, as embracing a truth which we merely suggest to our friends the mesmerists, without wishing, by any means, to urge it over zealously upon them:

Prudens futuri temporis exitum
Calliginosâ nocte premit Deus;
Ridetque si mortalis ultra
Fas trepidat—

And by referring our readers to a communication which they will find in another part of this day's Gazette, for some particular information upon young Alexis's powers of divination and second sight.

CLINICAL PRIZE REPORTS.

By H. FEARNSIDE, M.B.

University College Hospital, 1843.

[Continued from page 480.]

Causes.—The only circumstances which can be referred to as likely to have produced the disease, are, the greater amount of exertion which she had been obliged to make for some time preceding its development,—an inadequate supply of blood, and some degree of mental disquietude, occasioned by the circumstances of her family. This is so far in accordance with the generally received opinion, which ascribes considerable influence to depressing passions, or corroding cares, as the causes of this malady.

Again, the cessation of various processes going on in the healthy economy, during the whole, or the greater part of life, has been noticed as apparently an occasional cause of this disease. In the present instance, the menses had only ceased about four months previous to her admission into the hospital, and it was within this period that the most important symptoms had manifested themselves.

Prognosis.—Admitting the disease to be cancer of the stomach, the only question to be entertained related to the probable duration of the complaint, or the length of time which the patient might survive, and this, her extreme feebleness and emaciation pointed out, could not be protracted.

Little need be said respecting the treatment of what was too plainly an incurable disease: the combination of hydrocyanic acid and tincture of sesquichloride of iron, had the effect of removing the vomiting, and so conduced much to the patient's comfort. In spite of the means employed, she gradually sunk, and death took place from asthenia.

The appearances presented in the lungs on the post-mortem examination of the body were interesting: it was found that the physical signs observed during life had been produced by the presence in the apices of the lungs, of tuberculous matter, more or less advanced in a process of cure. On the left side, the tuberculous matter had been arrested in its progress, before the production of cavities, and converted into a chalky, plastery matter. The right lung appeared to exhibit the changes which tubercle sometimes undergoes when it has proceeded to a greater extent before a reparative process is set up: about an inch from the apex there was a cavity, lined by a membrane, and containing some putty-like matter: it is probable that the cavity had shrunk to some extent, and had then become filled by the remaining tubercular matter undergoing the cretaceous transformation. A similar case is described by Professor Rokitsansky, and is by him classed as the third method in which tubercle may become quiescent. It may not be uninteresting again to remark the entire absence of any general symptoms referrible to the lungs: there was no cough or dyspnoea, and no evidence of her having at any time been subject to cough.

The heart was found much atrophied, as is commonly the case in cancer, and the lining membrane of the aorta was raised by an opaque, and in some parts osseous deposit, beneath it, as is so commonly seen in those whose systems have begun to suffer from the weight of years, or the wear and tear of life.

The stomach was found much enlarged,

having given rise to the peculiar prominence of the abdomen observed during life. The condition of the os uteri was analogous to that pointed out by Dr. Montgomery as indicative of the incipient stage of carcinoma of that part.

[In the foregoing remarks, as well as in the comments upon the cases which may be published hereafter, the writer has availed himself of the clinical observations and lectures of the respective physicians under whom the cases occurred].

CASE II.—*Erythema papulatum, attended with considerable pyrexia; succeeded by jaundice; subacute inflammation of the gastro-duodenal mucous membrane; congestion of the liver; incipient phthisis; the hepatic affection relieved by mercury, purgatives, and alkalis.*

C. W., æt. 21, admitted into University College Hospital under Dr. Williams, May 11th, 1843. He is of dark complexion, moderately robust conformation, and ordinary stature; he spent the early part of his life in Kent, but for the last six years he has resided in London; he has always had a sufficiency of wholesome food, and has been in the habit of taking a moderate quantity of fermented and occasionally some spirituous liquor. His parents are dead; his father dying of dropsy, his mother of fever; neither were particularly subject to any disease, so far as he is aware; his brothers and sisters are healthy. His occupation is that of a book-binder; his work is laborious, and he is often employed from 6 A.M., to 9 or 10 P.M.; the room in which he follows his employment is hot, and he is particularly exposed to heat from his undertaking the gilding department, and working over a gas stove; he consequently wears but light clothing, and frequently goes into the open air without putting on any extra garment; hence he often suffers from coughs and colds, and has occasionally expectorated a little blood. He rarely or never takes any outdoor exercise during the week; upon the whole, however, his general health has been tolerably good, and he has not lately suffered from any severe attack: when about five years old he had an inflammation of the lungs, and when about ten, he had scarlet fever; since which time he does not recollect being laid up for more than a day or two at once, and from the effects of cold.

On last Sunday fortnight (April 23d), he spent part of the day at Hampstead, and having overheated himself considerably by walking and running about, he then took off his hat, and sat down upon the Heath to rest himself. On returning home he felt exceedingly cold, and shivered much, and after getting into bed he became very hot, especially about the extremities, and perspired

freely. During the following day he was languid, thirsty, and without appetite; at night his attention was directed to his feet, from the presence of a tingling sensation on them, and on examination he found them swollen, and covered with red pimples, which were distinctly elevated, so that the skin felt rough. On the following day the eruption extended in patches as far as the knees; the febrile symptoms continued, and in the evening he became so unwell that he was obliged to desist from his employment, which he has not since resumed; he did not, however, seek medical advice until two days afterwards, when he applied as an out-patient at University College Hospital. He was then found to be suffering from erythema papulatum; and a mixture of colchicum wine, and liquor potassæ, was prescribed for him; his legs were bandaged, and rest enjoined. The medicine occasioned considerable sickness: he began to suffer from severe pains in the limbs, and the eruption extended to the face and arms, and gradually covered the whole of the latter; after the lapse of two or three days, his bowels became relaxed, and the febrile symptoms subsiding, the disulphate of quinine was substituted for the medicine before mentioned. About this time he observed that his motions were very light coloured, and his urine of a very deep hue, like "saffron water." Not deriving much benefit from the quinine, it was discontinued, and the colchicum again prescribed on May 4th. Early on the following day the tunica albuginea of the eyes was seen to be of a yellow colour; in the after-part of the day he had rigors, followed by heat of skin, and in the evening the whole surface of the body had assumed a yellow colour. He did not suffer at that time from any pain in the right shoulder, or pain or tenderness of the right hypochondriac or epigastric regions, nor itching of the skin. On the succeeding day the hue of the skin had become deeper; some purgative medicine was given him; and on May 9th, a pill, containing calomel and the extract of colchicum, was directed to be taken three times a day. He has suffered considerably from nausea and sickness, tinnitus aurium, severe throbbing headache, and inability to sleep; he has had frequent shivering, especially in the after part of the day, succeeded by increased heat of the surface, and thirst; the eruption has been fading for some days past.

State upon admission.—The surface is warm; conjunctivæ, and skin generally, are yellow, but not deeply so; the centre of each cheek is marked by a dusky spotted redness; on the inner part of both forearms and arms there are a number of small papulæ of a yellowish brown colour, which is not much altered by pressure; on the dorsa of the feet there are the remains of some

papulæ, most distinctly seen on the left foot, on the back of which there is also a patch of erythematous redness, which extends upon the great toe; he has no pain in the limbs, but complains of being weak and languid; he is somewhat emaciated, but thinks that he had been losing flesh for some time before the present attack. He has no pain about the head, or giddiness; his countenance is rather heavy; he sleeps indifferently, and dreams much. He has no pain about the chest, and but little cough; his respirations are sixteen per minute.

Physical signs.—In respiration, the right side of the chest appears to move less than the left one, and vocal fremitus is more distinct under the right than under the left clavicle. On percussion, the upper part of the right side, anteriorly, is less resonant than the corresponding part of the left side; and the same difference is perceptible between the right and left supra-spinous fossæ. The expiratory murmur in respiration is more audible under the outer end of the right clavicle than under the same part of the left one, and it has a rather bronchial character. There is also increased vocal resonance, both under the right clavicle and over the right supra-spinous fossa, and the heart's sounds are heard under the right clavicle. Inferiorly and anteriorly there is considerable dulness on percussion below the fifth rib on the right side, and the respiratory murmur is feeble in the same situation. Posteriorly, the inferior half of the right side of the chest is dull on percussion, and the same part on the left side appears to be less resonant than natural; vocal fremitus is much more distinct upon the lower part of the right than of the left side, and the expiratory sound in respiration is distinctly audible in the former situation.

The pulse is 80, moderately full, and compressible; the heart's sound and impulse natural; the lips are dry and parched; the sides and tip of the tongue are red and smooth, with some of the papillæ considerably enlarged; the centre of the tongue is covered with a thin pale fur; he is very thirsty; has no appetite; experiences a constant sensation of nausea, and has vomited three or four times during the day; his bowels are rather relaxed; his motions light coloured and watery; there is considerable tenderness on pressure upon the epigastric region, especially towards its right side, and upon the right hypochondriac region, and he has occasionally rather severe pain in these situations; the liver does not extend beyond a finger's breadth below the margin of the ribs; the urine is high coloured, strongly acid, turbid from a deposition of the lithates, sp. gr. 1024; it is changed to a deep olive-green colour on the addition of nitric acid.

Treatment.—A combination of calomel, blue-pill, and extract of hemlock, was directed to be taken twice daily, and a senna draught in the morning; and the patient was placed upon low diet.

In the course of two days there was distinct evidence of the influence of mercury upon the system, the patient's gums being turgid and painful, and having a number of white films upon them. He did not suffer from any pain in the epigastric and right hypochondriac regions, except when pressure was made upon those parts; the skin was less yellow, and the eruption had completely disappeared. The pills were discontinued, and an alkaline medicine, containing Tartrate of Soda and Nitrate of Potash, prescribed. On May 17th, the discoloration of the skin was still further reduced, and the urine was found to be free from bile; the tongue was still smooth and red, but the vomiting had ceased, and the alvine evacuations had assumed more of their natural appearance. On May 19th there was but little pain on pressure over the upper part of the abdomen; and the enlargement of the liver, as indicated by the dulness on percussion over the postero-inferior part of the right side of the chest, was less obvious; he had no thirst, and his appetite was becoming good. A tonic medicine, containing Calumba and diluted nitric acid, was substituted for the saline previously given, and an aperient (Ext. of Colocynth), was directed to be taken every night. Under this treatment he rapidly improved, and was discharged cured on May 27th.

REMARKS.—Jaundice, for such was the affection under which this patient was suffering, is considered rather as a symptom than as a specific disease. Its essential element is the presence of bilious matter in the circulating fluid, and its deposition in the textures: this may occur in connection with a variety of causes and conditions of the system: it may result from mechanical impediments to the free passage of the bile into the intestines, such as tumors, a distended colon, or an enlarged gland pressing on the ducts; or the presence of gall-stones, or inspissated mucus within them; or from inflammation of their lining membrane: the same condition may be produced by inflammatory or congestive affections of the liver or alimentary canal, or by causes acting on the nervous system, mechanical, mental, or moral. In the present case there was no reason for suspecting the existence of gall-stones or tumors; the age of the patient, the gradual manner in which the attack supervened, its being unaccompanied by any severe, and especially paroxysmal, pain in the right hypochondriac region, were adverse to such a view; as also was the observation

of Dr. Bright, that in such cases the colour of the skin is of a very vivid hue, and acquired more or less suddenly. Again, the rigors, and other febrile symptoms preceding the attack, might have led to the supposition that an inflammatory affection of the liver had given rise to the jaundice, but on the patient's admission into the hospital there was no evidence of the existence of anything more than congestion of that organ. On the other hand, the symptoms were those of subacute inflammation of the upper part of the alimentary canal—viz. obstinate vomiting, everything but the mildest and lightest nutriment being rejected by the stomach; considerable thirst; a tongue with smooth red margins; pain and tenderness on pressure over the epigastric and right hypochondriac regions.

The congestion of the liver was pointed out by its rising higher than usual into the vault of the diaphragm, as indicated by the increased dulness on percussion over the lower, and especially posterior, part of the right side of the chest: it is possible that this may have been a sequel of the duodenal affection, and have concurred with it in giving rise to the jaundice; or it may have been a primary affection resulting from the exposure to cold.

The influence of inflammatory affections of the intestinal canal in giving rise to jaundice has been especially dwelt upon by Dr. Marsh; and a turgid and inflamed condition of the duodenal mucous membrane would appear to be a not uncommon cause of jaundice. The precise nature of the connection between this pathological state and the obstruction to the passage of the bile, has not, so far as the writer is aware, ever been demonstrated. A suggestion thrown out by Dr. John Hunter in his "Treatise on Army Diseases," is quoted by Dr. Marsh (Dublin Hospital Reports). He inquires, "Did the inflammation in the neighbourhood of the ducts, and perhaps extending to them, excite such contractions in them as obstructed the bile in the same way that suppression of urine is sometimes a consequence of inflammation of the urinary passages?" The muscularity of the ductus choledochus would seem to be proved as well by a consideration of its mode of origin, as a diverticulum from the intestine, as by actual experiment upon the lower animals; Müller having observed distinctly periodic contractions of the duct in a recently killed bird. Granting the applicability of these observations to the human subject, contraction of the ducts, or spasm of them, as it is usually termed, would cease to be a mere hypothesis. But, whether the proximity of an inflamed membrane, or the actual existence of inflammation in the duct, would give rise to such tonic and permanent contractions as must

be supposed to exist in these cases, is a question by no means settled.

The occurrence of the erythematous affection of the skin might be regarded either as owing to the close sympathy subsisting between the gastro-intestinal mucous membrane and the cutaneous structure, or as connected with imperfect action of the secreting organs in general, and liver in particular, and the consequent retention of excrementitious matter in the circulating fluid; the skin, in this case being peculiarly liable to be affected, from the previous state of high excitement in which its functions had been, succeeded by a state of collapse still further increased by exposure to cold.

On referring to the history of the case, we find that at the time at which the attack of jaundice came on, the patient was taking colchicum, and it becomes a question whether this might not have some share in the development of this additional symptom, as it has been frequently observed, that, under some circumstances, medicines, which in a normal state of the habit increase the flow of bile, bring on jaundice.

With reference to the *causes* of this attack: the patient was predisposed to hepatic disease from his being habitually in a high temperature, working in a close and hot room; again, his rash exposure of himself to a cool air when overheated by running, was a proceeding well calculated to give rise to internal congestion—probably the first link in the chain of morbid processes.

The *prognosis* in this case was favourable, from the youth of the patient, his previous tolerably good state of health, and from the view taken of the pathological nature of the affection.

The *treatment* consisted in the administration of small doses of mercury and extract of hemlock; a combination which appears to be peculiarly beneficial in many cases of defective action of the liver—with or without an inflammatory state of the gastroduodenal mucous membrane; purgatives were also given, and after a few days an alkaline medicine was prescribed; alkalies being useful apparently, both by their chemical action upon the bile, and by increasing the renal secretion, for when one excreting organ fails in its action others generally suffer also, and the connection between none appears more intimate than that between the liver and kidneys: a mild bitter was subsequently prescribed, and under this treatment he rapidly improved, and in the course of sixteen days was sufficiently well to leave the hospital.

The *diagnosis* of cases of incipient phthisis is a matter of some difficulty, but the combination of general symptoms and physical signs present in this case, renders it highly probable that there existed some tubercular

deposition in the summit of the right lung: We find that he was very subject to coughs and colds, from the alternations of temperature to which his employment subjected him; he had been getting thinner for some time before his admission into the hospital; on two occasions he had expectorated a little blood, and he had suffered from slight cough for a considerable time. The character of the physical signs strengthened the suspicion which the existence of these symptoms necessarily gave rise to; the motion of the right side of the chest was somewhat less free than that of the opposite side, there was an increase of the vocal fremitus, dulness on percussion, and bronchial respiration under the right clavicle and over the right supra-spinous fossa: the resonance of the voice was also distinctly increased over the same situations.

ARMY SURGEONS.—HEALTH INSPECTIONS.

To the Editor of the Medical Gazette.

SIR,

IN your number dated 21st of June, there are some observations by Dr. Hull, of Norwich, with respect to army surgeons, the concluding passages of which refer with honest indignation to that most disgusting and degrading business enjoined amongst the duties of army medical officers—the *health inspections*. Upon this subject I propose to offer a few additional remarks, trusting that you will not deem them unworthy of insertion in your valuable journal.

Your correspondent in a kind and sympathizing spirit observes, that “a civilian may fearlessly denounce what a soldier must not, through a sense of discipline, deprecate,” and this it is which has hitherto prevented all remonstrance on the part of army medical officers against so odious and useless a practice, notwithstanding the universal recognition amongst us of the efforts which have been so successfully made by our present enlightened and benevolent Director General, to increase the comfort, uphold the respectability, and advance the efficiency of the department. But this is a grievance to which probably his attention has never been directed, for the reason above stated, and as I cannot believe that he would continue to enforce a duty so utterly repugnant to the feelings of every gentleman, were he reminded of its humiliating effects, I hope I may succeed in thus attracting his notice, as it is evident from the late contributions he has forwarded to your journal that he is numbered among your readers.

The “*Health Inspections*,” as they are so misnamed, could scarcely be palliated

were they even productive of the utility to the service which their appellation would infer. But so odious and degrading are they considered throughout the army, that the detective measures which they are intended to enforce are utterly negated by the abhorrence and aversion of all parties engaged in them, from the medical officers down to the youngest drum boy. In many regiments the practice is a mere form hurriedly gone through, in which no attempt is made to effect one single object of the purpose intended; in others, where the discipline and supervision of the commanding officer may be more stringent, the disgusting duty is carried through, more in compliance with the standing orders, than with any attention to that minute scrutiny which could alone prove effective; but throughout the service, however zealous and indefatigable in all other respects the medical officers may be, this duty is performed with a degree of negligence and sullen reluctance which its sense of degradation must naturally produce. The soldiers are equally averse to so humbling an exercise of authority, and invariably attempt to evince their indignation and abhorrence by ill-concealed ribaldry and suppressed jokes, which may at least throw contempt on the revolting ceremony. In furtherance of this object, every trick and artifice which can be devised on their part to evade the detection of disease, are not only considered justifiable, but highly ingenious; and all those who can, by any scheme, absent themselves from the disgusting exhibition, invariably do so. Thus, from the universal abhorrence of these inspections, the whole proceeding is rendered a mere farce; and I may safely assert that a far greater number of syphilitics escape detection than are ever ordered to hospital, even when the medical officers scrupulously endeavour to discover them; and this, indeed, is a very rare case.

In short, no one who is acquainted with the *working* of this supposed precautionary measure can attempt to deny the utter inefficiency of it in practice; whereas, if no such odious injunction existed, a far more efficient system would soon be organized by the medical officers themselves, which, whilst it lightened the sick-list and their own labours, would entail severe punishment on those who, by concealing disease, should render its treatment more difficult and protracted. Under the present system, such delinquents, if they can succeed in proving their attendance at the weekly health inspections, escape all punishment, as the "Doctor" is of course expected to possess the eyes of Argus, and any oversights can only be attributed to his blindness or negligence; neither of which imputations he would of course willingly incur; therefore he is usually silent about men coming to

hospital when they are no longer able to remain out of it.

In conclusion, it is needless to observe what an admirable subject for sneering and sarcasm such a theme must always present to the malicious jocosity of young ensigns at a mess-table, nor does it appear possible that any plan could have been devised which would more thoroughly inspire contempt for the position of army medical officers when such is the humbling nature of his duties, whilst it is equally certain that nothing could so effectually and so constantly wound the feelings of the degraded

ARMY SURGEON.

July 10, 1844.

ON THE AMOUNT OF PERSPIRATION FROM THE HUMAN BODY.

BY PROFESSOR VALENTIN.

THE distinguished physiologist of Bern has given an account of some statical experiments which he made upon himself, apparently with much care, in the last number of his *Repertorium*, which has just reached us, and which contains, we may add, the conclusion of an extended and valuable Report on the Progress of Physiology during the year 1842. The experiments on perspiration are not only curious in themselves, but they are interesting as introducing us in some sort to the privacy and particular acquaintance of a man whom all who have lately followed the development of medical science in its foundations have for so many years held constantly in their eye.

The balance employed was a very delicate one, which loaded with from 108 to 110 kilogrammes, or about a cwt. in either scale, still turned upon the addition of half a grain.

The weight of the professor, completely naked, was taken repeatedly,—as often as fifteen times in the course of twenty-four hours; the temperature of the room did not vary more than a degree and a half Cent. at different times; it was at from 20° to 21°, 5 of this scale. Every thing taken into the body, as well as every thing given out from it, was of course weighed either directly or indirectly. The weather during the first day's experiment was misty; during the other days it was fine.

First experiment, September 4th, 1843.—Weighed fasting at 6h. 44m., and again, having taken two cups of coffee, at 7; again at 8h. 22m. having been engaged in writing, and having smoked a pipe—the professor smokes!—and again at 8h. 40m. having meantime shaved, made water, and gone to stool; again at 10h. 34m. having been walking in the hot sun and perspiring, and feeling very hungry—it is pleasant to hear a

man of science say he is hungry ! much enjoyment at thy approaching meal Herr Professor ! Again at 11h. 55m. after having breakfasted quietly, written, and smoked another pipe—does the professor approve of smoking regularly after meals ? again at 12h. 55m. immediately after dinner, which consisted of soup, sausage, veal, salad, potato with butter, and a very little drop of wine—like all philosophers we see the professor is a temperate man ! Let us see whether or not he made a good dinner ; immediately before his meal he weighed 52,687 grammes ; immediately after it, 53,467 grammes ; difference 811 grammes, which is as nearly as possible 25 ounces—yes, the professor dined well—"may good digestion wait on appetite !" say we.

Afternoon.—Weighed at 1h. 40m. having walked a little, but for the greater part of the time having lain upon the sofa smoking a cigar. Why this is quite luxurious ! but though we have no such *otium* in this crowded metropolis ourselves, we are far from grudging the worthy professor his repose ; doubtless the writing on which he had been engaged was part of the Report on the Progress of Physiology for the past year, that must evidently have been a tough piece of work. Urine was passed a second time of sp. gr. 1,0138 ; at 2½h. a draught of water was taken. Weighed again at 3h. 2m. having sat tranquilly engaged in writing—doubtless the "Report ;" at 3½h. and at 4h. a second and a third draught of water. We fear the sausage must have been highly salted and spiced ; the professor is evidently thirsty. Weighed again at 4h. 52m. ; engaged as before, and having made water at 4½h. of sp. gr. 1,017. ; weighed again at 5h. 57m. after walking for an hour in the sun, having perspired a little and become extremely hungry. Walking in Switzerland, we know by experience, does not take away the stomach ; we wish fagging in London did not, but it does sadly. Weighing repeated at 6h. 38m. the appetite having been appeased with a supper of veal, bread and butter and cheese, and a glass of water. The evening meal weighed 525 grammes, or about 16½ ounces. For between two and three hours the professor took active exercise, having clambered up and run down two very steep mountains, so that he perspired freely—until his shirt was soaked. At 9h. 23m. the weighing was repeated. Between nine and ten a draught of water was taken, and urine passed of sp. gr. 1,002 ; to complete the twenty-four hours the weighing was performed for the last time next morning at 6h. 38m. We see, therefore, that the professor goes early to bed and that he rises early, for he had been at work writing—the Report—half an hour before the morning's weighing.

We have as results of the whole, that the weight of the body varied at intervals in the day, between 52909 and 53759,5 grammes. The weight of the whole meat and drink consumed was 3199,1 grammes ; the excretions were :—

Fæces	. . .	214,5 grammes
Urine	. . .	1041,8 "
Perspiration	. . .	1630,8 "
		2887,1

312 grammes were therefore taken in more than were given out.

The quantity of food consumed for each hour was 133,3 grammes.

Of fæces passed	. . .	8,9 "
Of urine	. . .	43,4 "
Of perspiration	. . .	67,1 "

If the *assumpta* be taken as unity then will the fæces be represented by 0,067

The urine	. . .	0,326
The perspiration	. . .	0,509
What has been retained	. . .	0,098

We shall not go over the second nor yet the third day's experiments, but add their general results in a tabular form of mean hourly quantities in grammes.

Day's food.	Fæces.	Urine.	Perspirat.
1 133,3	8,9	43,4	67,1
2 115,8	6,4	57,7	48,4
3 116,4	8,5	79,7	39,5
Mean 121,8	7,9	60,3	51,6

Professor Valentin also tried the loss by perspiration during the night. In 10 hours 18 minutes, between the 8th and 9th Sept., he lost 411,5 grammes in this way ; or on an average 39,95 grammes : as nearly as possible f3x. per hour. On another occasion he lost on an average at the rate of 40,7 grammes per hour ; on a third the loss was 34,8 grammes per hour ; on a fourth, a fifth, and a sixth, 31,9, 38,1 and 41,1 grammes per hour.

Very great differences in the quantity of perspiration thrown off are observable from hour to hour ; rest and motion are the grand conditions that influence the quantity. The loss having been 90,5 grammes per hour by perspiration under the use of exercise in the sun, is reduced the following hour by rest, and occupation in writing, to 47,4 grammes per hour. During another hour spent in the same way, it is no more than 32,8 grammes ; but by and by, under violent exercise, it rises to 132,7 grammes per hour.

No distinction, it is proper to observe, is made between the loss from the general surface of the body and from the lungs ; the weights given appear to include both the pulmonary and cutaneous exhalations.

CASES OF OVARIAN DISEASE.

BY EMERY BISSELL, M.D.

DR. BISSELL details the post-mortem appearances in three cases of ovarian disease that terminated fatally after the usual temporizing treatment by tapping had been gone on with for longer or shorter periods. In the first case the patient appears to have died of peritonitis, the consequence of the last tapping; so, probably, did the second. The cause of death in the third instance is not named, but it was probably exhaustion, as in the other cases, brought to a crisis by tapping. In none of the three cases was the body of the uterus diseased; and the attachment of the ovarian tumors was, in every instance, by a small pedicle, not more than an inch in diameter. In none of them were there any material adhesions to the adjacent tissues, certainly none to hinder a speedy and ready removal of the diseased masses. In case No. 1, the left ovary weighed 19 lbs., the right ovary 1 lb.; in case No. 2, the left ovary weighed 11 lbs., the right 8 ozs.; in case No. 3, the left ovary—its solid and membranous parts alone weighed 37 lbs.; the quantity of fluid discharged from it 35 lbs., not reckoning 10 lbs. which were estimated to have been lost on the table and floor: the whole weight, therefore, must have been about 82 lbs., to which may be added 11 lbs. of fluid drawn off by tapping the day before death, the whole of which could hardly have been reproduced. The right ovary weighed half a pound. [Dr. Bissell declares himself as decidedly favourable to the operation of ovariectomy. The uniformly fatal tendency of ovarian disease justifies, in his apprehension, the procedure, were the results even less favourable than they have been.]—*American Journal of Medical Sciences*, April 1844.

TREATMENT OF LEUCORRHOEA

BY MEANS OF

TINCTURE OF IODINE.

M. VAN STRKENISTE has made use of a dilute tincture of iodine with great success in cases of obstinate chronic leucorrhœa.

R. Iodine, gram. iv.; Alcohol, gram. lx. solve; et Aquæ destill. grammes cxxv.; about 30 fluid grammes (or f3xv.) are to be thrown into the vagina as an injection, and repeated every day, or every other day, according to the excitement it occasions.—*Ann. d'Obstétrique, cited in Gaz. des Hôpit.* No. 65.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

On the 30th inst., it is said that the Fellows of the Royal College of Surgeons of England are to meet for the purpose of electing three new Members of Council.

William B. Carpenter, M.D. F.R.S. was, on Monday last, elected Fullerian Professor of Physiology to the Royal Institution of Great Britain.

Died, at Carlisle, on the 9th inst., aged 34, William Elliot, M.D. To professional attainments of a high order he added unwearied zeal in the pursuit of science. He was an able, judicious, and humane practitioner. In all the relations of private life he was truly exemplary; and his early removal from a sphere of great honour and usefulness will be long and sincerely deplored.

"Medicus, Clifton."—The work referred to by Medicus will appear very shortly.

APOTHECARIES' HALL.

Gentlemen who have obtained Certificates,
July 4.—H. J. Aldham, Witham, Essex.—W. M. Pulleyne, Norfolk.—G. M. C. Saunders, Honiton, Devon.—G. F. Wills, Crewkerne, Somerset.

July 11.—W. Davy, Barnstaple, Devon. C. Rogerson, Blackburn, Lancashire.—J. H. Wise, Banbury, Oxon.—S. S. Alford, Taunton, Somerset.—J. Stevens, Wolverton, Hants.—E. K. Parson.

MORTALITY OF THE METROPOLIS.

Deaths from all causes registered in the week ending Saturday, July 6.

Dropsy, Cancer, Diseases of Uncertain Seat	98
Diseases of the Brain, Nerves, and Senses	137
Diseases of Lungs and Organs of Respiration	228
Diseases of the Heart and Blood-vessels	27
Diseases of Stomach, Organs of Digestion, &c.	78
Diseases of the Kidneys, &c.	2

REPORTS
OF
CASES TREATED IN UNIVERSITY
COLLEGE HOSPITAL.

By H. FEARNSIDE, M.B.

With Clinical Remarks by
DRS. WILLIAMS, TAYLOR, AND THOMSON.

Extensive anasarca, with albuminous impregnation of the urine; presence of urea in the blood; bronchitis; condensation of some parts of the tissue of the lungs; enlarged liver; treatment by local and general bleeding, hydragogue purgatives, and diaphoretics.

THOMAS CRAWLEY, æt. 32, admitted into University College Hospital, under Dr. Williams, June 20th, 1843. He is a stout, muscular man, rather below the middle stature; he is married; his occupation is that of a labourer in some livery-stables; he is employed principally in washing carriages, &c., and is consequently much exposed to cold and wet. He is in the habit of living freely, and has never suffered from privation; he frequently takes animal food twice a day, and is not particularly temperate in the use of intoxicating liquors, generally taking three or four pots of beer daily, and occasionally more, besides an allowance of spirits. His mother died of consumption; his father of some acute disease, brought on, he believes, by drinking; out of 14 or 15 brothers and sisters 3 only are living; the greater number having died in infancy and childhood.

His general health has been very good; he has no recollection of having had any serious illness, except when about 15 or 16 years of age; at this time he had inflammation of the brain, for which he was about two months in the Marylebone Infirmary.

His usual practice has been to take a "siesta" in the hay-loft for an hour or so in the afternoon. During the last, and the early part of the present month, he was much

exposed to rain, &c., and he thinks it not unlikely that he may have lain down to sleep in his damp clothes, or upon damp straw; his health, however, does not appear to have been *sensibly* affected until about eight days ago, when upon awaking in the morning he found his face swollen, especially upon the left side, but not red or inflamed. On the same day his breathing became rather difficult, and he experienced a sense of weight and oppression about the chest; he began to cough and expectorate a thick yellow fluid; he also became hot, and thirsty; his urine was high coloured, but never contained any blood (so far as he is aware); he had no difficulty in voiding it, nor had he any pain about the loins. These symptoms were not sufficiently severe to prevent his attending to his employment, which he continued to follow during the week; but his cough became worse, and he suffered from headache, especially towards night. Two days ago, he "thought" that his legs were swollen; the symptoms before mentioned continued up to the time of his admission.

Present State.—The surface generally is cool and dry; the legs and thighs are tense, and very oedematous; the integuments of the abdomen and walls of the chest are also oedematous, but the arms are not affected. The face generally, and its left side in particular, are swollen and puffy, and the impression of the finger does not immediately disappear; but there is no distinct "pitting" upon pressure; the swollen parts are not in any degree painful. The ocular conjunctiva, especially that of the left eye, is considerably ecchymosed. The skin of the lower extremities is marked by a great number of discoloured spots from bruises, and there are also many small reddish pimples, some of which are covered with blackish scales, as if from a drop of concretion blood.

He complains of a sense of heaviness, and some pain about the head; he has a disposition to sleep more than usual; the countenance has a heavy expression.

His voice is rather hoarse; he coughs frequently, but has no pain about the chest; he complains, however, of a sense of fulness; he expectorates a considerable quantity of a thin brownish fluid, with portions of mucopurulent matter floating in it.

Physical Signs.—There is not much difference in the motions of the two sides of the chest, but the sound on percussion under the left clavicle is somewhat duller than that elicited under the right one; the respiratory murmur is rather feeble than natural under both clavicles, and that accompanying expiration is more audible than natural under the left one. The postero-inferior parts of both sides of the chest are not very resonant on percussion, and this applies more especially to the left side. Over the middle and lower parts of the right back a submucous rhonchus is heard; on the opposite side the respiratory murmur is in some parts rough, and in others a mucous rhonchus is heard; as also over both supra-spinous fossae. Respirations 20 per minute; pulse 75, moderately full and firm; the sounds and impulse of the heart are natural. The tongue is covered with a thin, pale fur; he is rather thirsty; his appetite is tolerably good; the bowels open; the urine scanty, high-coloured (from the presence of hæmotosin), its reaction is acid; sp. gr. 1023, and it contains a considerable quantity of albumen; after being tested by means of heat and nitric acid the coagulum amounts to one-third of the volume of the fluid operated upon. The liver appears to be considerably enlarged, extending down into the abdomen, about three fingers' breadth, or rather more, below the margin of the ribs; there is also considerable dulness on percussion over the left hypochondriac region, as if from some enlargement of the spleen. He has no pain or tenderness about the loins.

Treatment.—Soon after his admission, a dose of calomel was given, and followed by a draught of infusion of senna; twelve ounces of blood were taken from the arm; the patient was directed to take an ounce of the bitartrate of potash every morning, and he was placed upon middle diet. On examination by Dr. Garrod, urea was found to be present in the blood—a quarter of a grain of the nitrate being contained in one ounce of serum; 1000 parts of urine were also found to contain 4·8 parts of albumen. For some time the cough continued to be the most troublesome symptom, but its violence and frequency were much reduced by the abstraction of 13 oz. of blood from the interscapular space by means of cupping. The urine remained scanty for some days, the quantity voided daily averaging, as nearly as could be ascertained, about thirty ounces; but after he had been five or six days in the hospital, it became more abun-

dant, amounting to about three pints in the twenty-four hours; it lost its impregnation with the colouring matter of the blood; its specific gravity fell, ranging between 1014 and 1018, and the quantity of albumen present in it diminished to a greater extent than was accounted for by the increased quantity of fluid excreted. The bowels were freely acted upon by the bitartrate of potash, which at first only occasioned some slight sickness. The oedema gradually, but rather slowly, diminished; the countenance became less heavy and soporose, and the patient experienced less disposition to sleep than on his admission. On account of the dryness of the surface, ten grains of Pulv. Ipec. Co. was prescribed to be taken at bed-time, after the patient had been under treatment for about a week. But his sensations had improved so much by this time that he could not be persuaded that there was any necessity for a longer residence in the hospital, and he consequently left it, after having been an inmate of it about nine days.

REMARKS.—The nature of the disease in this case was apparent from a very slight examination of the patient. The puffiness of the face, the extent of the oedema, the suddenness of its appearance, the fact that the face was the part which first began to swell, the habits of the patient, his habitual indulgence in very free potations of intoxicating liquors—all these positive circumstances being confirmed by the absence of any evidence of disease of the heart, gave a very high probability to the opinion that the dropsy depended upon disordered function of the kidneys, and the non-elimination of urea from the blood. This supposition was established by a chemical analysis of the blood and urine; the former was found to contain urea, and the latter albumen. The disease under which the patient was suffering was the *acute* form of albuminuria; the symptoms which ushered in the attack, the thirst, heat of skin, headache, &c., were such as announce the commencement of an acute disease. The character of the urine was another proof of the same fact; it was scanty, high coloured, from the presence of hæmotosin, of by no means low specific gravity, and largely impregnated with albumen. The swelling of the face, although more considerable, perhaps, than is generally seen in oedema of this part from albuminuria, was, no doubt, owing to the same cause as the oedema of other parts of the body; for there was an absence of any local disease to explain it; it was not attended with the usual signs of inflammation, and it had that peculiar *elastic* character, not distinctly pitting upon pressure, which has been noticed, and is adverted to by Dr. Christison, as connected with that pathological com-

dition of the kidneys of which the general oedema is a consequence. The heaviness of the countenance, and the great disposition to sleep manifested by the patient on his first entering the hospital, must be attributed to the same cause as the oedema, the circulation of urea in the blood being a slight degree of the same state which, in its more developed form, is seen as coma, or apoplexy.

The bronchitis from which the patient was suffering, if not dependent upon the vitiated character of the blood, was probably, at any rate, influenced and maintained by it. It appears rational to suppose that blood containing an excrementitious matter must more or less irritate, and otherwise modify, the functions of different parts, and thus render them more susceptible to impressions from external causes.

There was evidence (in the dulness on percussion, and altered character of the breath sound), of some condensation of the pulmonary tissue, especially upon the left side of the chest; the situation of that in the upper part of the lung might suggest its being due to the presence of tuberculous matter, and this is rendered more probable from the fact of the patient being hereditarily predisposed to phthisis, as well as from a consideration of his mode of life. The condensation of the lower parts of the lungs might be the result of inflammation, or effusion of serum into the pulmonary tissue: as the dulness on percussion was not very marked, and was unattended by any bronchial respiration, the latter is probably the correct explanation. Considerable enlargement of the liver existed in this case; it was unattended by any pain or tenderness, and was probably of some duration, and owing to the continued influence of intoxicating liquors.

The patient experienced little or no pain or tenderness about the swollen parts; it must be remarked, however, that he was a heavy, phlegmatic subject, constitutionally possessing but little nervous sensibility, and his whole mode of life and occupation would have anything but a tendency to develop the little he originally had; every part of his frame appeared to have the same unimpressible character; hence, probably, the absence of pain; hence also, the little constitutional suffering in this really so serious disease.

The origin of the disease in this case may fairly be attributed to the patient's habits and mode of life; his large consumption of fermented and spirituous liquors, and his almost constant exposure to cold and wet. From the operation of the former causes, the secreting powers of the kidneys are habitually taxed to get rid of the superfluous amount of fluid daily thrown into the circulating system; a fluid not consisting of simple water, but holding in solution or admixture

various innutritious and noxious matters, which cannot fail to make some impression (no doubt, of an injurious character) on the secreting apparatus of the emunctory by which they are discharged; and which being repeated, must either directly lead to the production of disease, or produce a state highly favourable to its development, on the application of other exciting causes. Again, one of the most powerful and constant effects of cold is the production of internal congestion, and in this the kidneys share; their secreting power, however, has already been taxed to the utmost,—their vital properties more or less impaired, and they are ill adapted to bear the extra quantities of blood thrown upon them. Under these circumstances, it would appear that the most exposed and unprotected vessels, those of the corpora Malpighiana, sometimes give way, and allow blood to be discharged with the urine; or if this is not the case, the serum of the blood transudes, and mingles with the fluid. Moreover, the true secretory functions of the kidneys—those consisting in the production and bursting of the cells along the parietes of the ducts—are also interfered with; hence the amount of solid matter discharged by the urine is lessened, and even some of the excrementitious materials which exist ready formed in the blood are not eliminated; and hence various injurious results ensue, some of which have been already enumerated as occurring in the present instance. The state of the kidneys, therefore, in the early stage of this disease, appears to be simply one of congestion in at any rate the majority of cases; theoretical reasoning would lead to this conclusion, and morbid anatomy confirms it. Many of the symptoms present in the progress of the case would not be easily accounted for on the supposition that the essential part of the disease is an inflammation of one or both kidneys; the cool skin, slow pulse, and absence of any pain or tenderness about the loins, are symptoms which we should not expect in inflammation of so important an organ.

The prognosis in this case cannot be considered favourable. Had the patient been tractable, and remained a sufficient length of time under treatment, there is every possibility that he would have been cured, supposing the disease not to have advanced beyond its first stage; but returning to his employment and old habits before the functions of the kidneys have been fairly reestablished, exposed to the same influences which caused the first appearance of the disease, we may anticipate its continuance and increase, and that it will either recur in a more intense form, or, gradually progressing, that it will, if more slowly, yet not the less surely, undermine

the constitution by more and more impairing the quality of the circulating fluid, causing the development of disease in other organs; or, if life be not terminated in this gradual manner, the patient may be rapidly carried off by the supervention of some acute disease, which, though it might be of comparatively little danger to a healthy subject, yet becomes fatal in the extreme to those whose excreting organs are thus disabled; for as the kidneys are the emunctories by which various noxious matters are eliminated from the system, (apparently) critical evacuations take place in acute maladies; when thus affected, they are unable to take on this increased action.—(Dr. Williams).

The treatment in this case consisted in bleeding, to diminish the morbid mass of blood, and also to reduce any tendency to secondary inflammations; hydragogue purgatives were then administered, which are useful by lessening the quantity of the circulating fluid, deriving to the intestines, lessening renal congestion, and thus enabling the kidneys to return to their healthy action. On June 24th the patient was cupped between the shoulders to relieve the bronchitic symptoms, and a few days afterwards Dover's powder was prescribed, so as to determine freely to the surface. Had the patient remained under treatment longer, a diuretic would probably have been of use; for although remedies of this class are condemned by some physicians, on the ground that they add to the irritation in the kidneys, the restriction cannot be held binding except during the presence of acute symptoms, or while the disease is in an early stage. In therapeutics it is frequently observed that a stimulant is one of the best applications to congested parts; illustrations of this in the treatment of the diseases of the external parts of the body are numerous, and the analogy may fairly be extended to internal organs.

Acute articular rheumatism—No affection of the heart—Rapid and successful treatment by bleeding, calomel and opium, colchicum, and purgatives.

Elizabeth Connor, æt. 35, admitted into University College Hospital, under Dr. Williams, May 10th, 1843. She is a woman of rather slight conformation, pallid complexion, and melancholic temperament. She is a native of the county of Cork, in Ireland, but has resided in London for the last sixteen years; she has always had a sufficiency of food, and has occasionally, but not habitually, taken some fermented or spirituous liquors. She is married, and has had seven children, two only of whom are living. The catamenia did not appear until the age of 22 (two years after her marriage), but her general health did not suffer in consequence. She resides in a damp house, and

in a close and confined street in St. Giles's. For the last few months she has been much exposed to the weather, having kept an open shop for the sale of coals, &c. Her father died of fever; her mother is still living, at a very advanced age, and in the enjoyment of good health. She has eight brothers and sisters, who are all healthy; and neither they nor her parents, so far as she is aware, have ever suffered from rheumatism.

The patient suffered from three attacks of fever before she left Ireland; but with these exceptions her health has always been good.

The present attack commenced four days ago, and without any particular previous exposure to cold or damp. At the time mentioned she began to suffer from pain in the knees, at first transient, but soon returning with increased violence, and attended with heat of skin, thirst, and other febrile symptoms. On the following morning (three days ago) the knees were still more painful, and the skin was red in spots, as was also that over the fronts of the thighs and legs. The knuckles of the left hand were swollen and painful, but not red; and she had severe pain in the back of the neck. These symptoms continued throughout the day, and greatly impeded, but did not entirely prevent motion. On the ensuing day, however, she became completely unable to move; the knees were at this time swollen, and she had excruciating pain in them; also in the right hip, and in the small joints, and back of the left hand. Her friends thinking that she would be relieved if she could perspire freely, gave her hot gruel and rum, and covered her with clothes for an extent which seriously interfered with easy respiration. In pursuance of the same system she was yesterday immersed in hot salt and water for some time, and hot fomentations were applied to the painful joints. But although she perspired profusely, none of these measures afforded any relief.

Present symptoms.—The surface is warm and moist; a strong sour odour is exhaled from the patient, and the perspiration is distinctly acid to test-paper. She complains of exceedingly severe pain in the right hip-joint, and in both knees, which are much swollen, the effusion appearing to be seated as well in the bursa around the joint, as in the capsules; the integuments in these situations are slightly reddened; she has no pain about the ankles, or large joints of the upper limbs, but the articulations of the fingers of the left hand are somewhat enlarged and painful.

The countenance is expressive of much anxiety, and the face is pale. She has no headache or giddiness, but complains of inability to sleep. She has no pain about the chest; no cough or dyspnoea; respirations 20 per minute; pulse 104, and rather sharp;

the sounds on percussion and auscultation, both over the lungs and heart, are healthy. The tongue is covered with a thin fur, through which enlarged papillæ are to be seen near its tip and margins. There is much nausea and disposition to sickness, but no actual vomiting; no thirst or appetite. The liver does not extend more than an inch below the margin of the ribs, nor does it rise higher into the thorax than natural. The bowels are moderately open; the urine scanty, high coloured, strongly acid, sp. gr. 1029, turbid from a deposition of the lithates, and it contains an excess of lithic acid. The catamenia have not been present for some months (since her last confinement); the mammae are large, and contain a number of small, indurated, and very painful tumors.

Treatment.—Twelve ounces of blood were taken from the arm; a pill containing five grains of calomel, and half a grain of opium, was directed to be given immediately, and repeated at bed-time. A purgative of sulphate of magnesia and infusion of senna was prescribed for the following morning, and a draught containing colchicum wine and tartrate of soda to be taken three times daily. The patient was also placed upon low diet.

12th.—The pain and swelling have almost disappeared from the left knee, but she thinks that the pain is rather increased in the opposite one, and also in the right hip-joint. She perspires much, has some headache, and sleeps but little. She complains of a feeling of oppression about the chest, prompting her to sigh frequently, but both the breath and heart-sounds remain healthy. The bowels are rather confined; the urine has the same characters as on her admission; the blood abstracted two days ago is highly buffed and cupped, and the coagululum is small and firm.

13th.—The rheumatic symptoms are much less severe; the swelling and pain of the joints have subsided in a great degree, so that the patient has been able to walk about the ward. She complains of pain about the lower part of the sternum, but there is no tenderness on pressure in this situation; there is nothing abnormal in the sounds or impulse of the heart; pulse 96, soft, and rather small; respirations 28 per minute. She has a good deal of headache and heaviness about the eyes. The tongue is covered with a thick yellow fur, and she has a constant disposition to vomit; the bowels have been confined for two days; the urine is clear, high coloured, acid, sp. gr. 1032; and it contains a large excess of urea and also of lithic acid. (The purgative to be repeated.)

15th.—There is no swelling of the joints, but she has some pain in the right popliteal space and over the trochanter major; she perspires less; pulse 88, soft and small; no oppression about the chest; the tongue

cleaner; the bowels open; the urine less high-coloured, and no longer contains an excess of urea. (Three grains of iodide of potassium to be added to the draught.)

17th.—She complains loudly of weakness and giddiness, has occasional tinnitus aurium, and the sensation of scintillations before the eyes; she has also considerable headache. No return of the rheumatic symptoms; the tongue is rather furred, and she occasionally suffers from sickness. Bowels open, and the urine natural; pulse 84, soft, and rather weak.

She appeared uneasy and dissatisfied, and left the hospital in the afterpart of the day.

REMARKS.—The peculiar characters which different diseases stamp upon the countenance, are nowhere better illustrated than in an attack of acute rheumatism; in fact, the countenance, posture, and general aspect of a patient labouring under this disease, are often alone sufficient to characterise it. The strong acid odour exhaled from the person of a rheumatic patient, is a sign which, in many instances, appeals powerfully to another sense. The truth of these observations was strikingly exemplified in the present case. The impression which a first view of the patient was calculated to give, was confirmed by a consideration of her age, the sphere of life in which she had moved, the nature of what appeared to have been the exciting causes of the disease, the situation of the joints affected, and the character of the accompanying fever.

With reference to the variety of rheumatism which existed in this case, the disease assumed chiefly the form of the diffused "articular,"—the synovial membranes, and the bursæ around the joints, being principally affected; and soon after the patient's admission, the principal part of the inflammation appeared to be in the latter structures. But, from the back of the hand being implicated, and from the pain experienced in the front of the thighs and popliteal spaces, the inflammation would seem to have also slightly affected the fasciæ, thus uniting the characters of fibrous and articular rheumatism.

In this as in many other cases of rheumatism, we find that the disease appeared to be rather produced by causes which had been long in operation, than to be the result of one solitary exposure; and this is easily intelligible on the most approved view of the pathology of the complaint. Regarding it as intimately and essentially connected with an excess of lactic acid, or some of its compounds, in the circulating fluid, it is nothing more than we should expect, that the slighter degrees should exist without giving rise to any very characteristic symptoms, and that only with its increase should they become prominent. This all agrees

with an observation which has been frequently made, viz. that the health has been failing for some time before a rheumatic attack.

Considerable difference of opinion has for some time existed as to the best mode of treating rheumatism; and this has been manifested by corresponding diversity of practice. Some treat the disease on general principles alone, whilst others resort to specific modes; and colchicum, mercury, diaphoretics, opium, nitre, and alkalies, are by turns recommended. Under such circumstances, our only resource is an appeal to experience. A sufficiently extensive series of observations as to the efficacy of some of these modes of treatment appears to be yet wanting, to enable us to form a correct opinion as to their value. It is in respect to this subject that the present case derives its importance, as it may be taken as a fair example of the course of the disease under the remedial agencies employed in this instance.

In accordance with a common practice, the patient had been under the influence of stimulants and sudorifics for some time before admission, but without benefit; the failure of this mode of treatment the writer has seen strikingly exemplified in many cases of acute rheumatism during the past winter. After her admission into the hospital, blood was abstracted from the arm; this is useful by diminishing the irritability of the heart, lessening the quantity of the circulating fluid, and also reducing its stimulating qualities by favouring absorption. The common antiphlogistic combination of calomel and opium was then given, and followed by a purgative; the system being thus prepared, the rest of the treatment consisted in the administration of colchicum, with small doses of a neutral salt, to which, near the conclusion of the case, and after all active symptoms had subsided, iodide of potassium was added. Under this mixed plan of treatment, the improvement of the patient was most rapid;—in three days from the period of its commencement, she was able to walk, and on the following day she was almost completely free from either swelling or pain of the joints; so that all acute symptoms had subsided in eight days from the date of the attack. The patient was left somewhat debilitated, as might be expected, but an improved scale of diet, and another week's residence in the hospital, would, no doubt, have sufficed for the complete re-establishment of her health.

It would appear unfair not to attribute a considerable share in the success of the treatment of this case to the colchicum, since, after the first day, it was the *sole* active agent employed, and the improvement in the state of the patient only became striking on the third and fourth days after the treatment

was commenced. It has been asserted by some physicians, *e.g.* Chelius, of Heidelberg*, that colchicum, when given in rheumatism, increases the quantity of uric acid in the urine; in the present instance, whether as an effect or a mere coincidence, it is certain that after the exhibition of the remedy for three days the quantity both of urea and of uric acid in the urine was largely increased.

It may be observed, also, that throughout the progress of the case, there was a disposition to constipation, although the colchicum was combined with small doses of a purgative salt, thus showing that the beneficial effects of that remedy cannot be (invariably) ascribed to its action upon the bowels.

CASES OF FRACTURE OF THE MAXILLÆ; WITH OBSERVATIONS.

By W. LYON, Esq.

Lecturer on Surgery, and lately one of the Surgeons of the Glasgow Royal Infirmary.

(For the Medical Gazette.)

CASE I.—Compound fracture of superior maxilla, with much displacement—Symptoms of concussion of brain—Recovery.

SEPTEMBER 25th, 1841. Robert M'L., aged 46. Three days ago, while the patient stood with his face turned upwards, a stone fell from a height of 160 feet, and inflicted a wound three-quarters of an inch in length, which passed through the substance of the upper lip of the left side, and fractured and detached, with the exception of slight soft connections, nearly an inch in each direction of that part of the alveolar arch of the superior maxilla into which the incisor teeth and dens cuspidatus are inserted. The eyelids are ecchymosed, and the patient is occasionally incoherent. The pulse and pupils are normal. Before admission attempts had been made to retain the fragment in its situation by placing a piece of grooved wood between the teeth, and fixing the lower jaw; but during the paroxysms of insensibility the patient removed the apparatus. He continued in much the same state for several days, and either would not permit, or immediately made nugatory, any means used for the retention of the fragment *in situ*. The pulse afterwards rose, the incoherence was not diminishing, and complaints were made of headache. The bowels

* Medical Gazette, vol. II. p. 680.

were freely opened; 14 ounces of blood were taken from the nape of the neck by cupping, and a cold lotion was kept constantly applied to the scalp.

The incoherence very speedily subsided after this; the fragment was then kept in its place by attaching it to the adjoining teeth by means of fine wire, and supporting it upon the teeth of the lower, pressed constantly against those of the upper jaw. The fragment soon united, and the patient was dismissed with very little deformity.

The only points worth noticing in the above case are, the mental incoherence, and the nearly complete separation of the fragment of the jaw; the reunion of which was nevertheless successfully accomplished. The incoherence was referred to slight concussion, and as it was expected to subside, it was not prescribed for until reaction took place; when the bleeding, purging, &c., immediately dissipated all the unfavourable symptoms.

It had been proposed to remove the fragment of the jaw previously to the admission of the patient into the Infirmary; but the relations fortunately refused assent.

The event shows the impropriety of the measure contemplated; for although the connections with the soft parts were so slight and so ragged that the fragment dangled loosely in the mouth, they were sufficient to maintain vitality, and after replacement, to secure the restoration of the functions of the part, and at last the perfect union of the bone. Had the piece even been completely detached, I believe that it would have been good practice to have attempted its reunion; and we have warranty enough, in well attested facts, to lead us to conclude that in all likelihood it would have become fast.

CASE II.—Compound fracture of lower jaw.—Treatment of wound by suture—separation of lips of wound—union by second intention—cure.

Daniel M. L., a carter. 15th November, 1841. Last night received the kick of a horse on the lower jaw. A ragged, lacerated wound, extends through the lower lip from its margin to the point of the chin, where the bone is exposed and fractured. A portion of the inferior alveolar ridge is likewise

fractured. Many of the teeth are loosened, and all the front ones of the upper maxilla are knocked out.

Two stitches were placed in the lips of the wound; the loose teeth of the lower jaw were fitted into grooves made in a piece of cork, which was cut long enough to extend over several of the unloosened teeth on either side, and motion was prevented by a four-tailed bandage. The patient was purged, and kept on low diet, having nothing but spoon meat. On the 19th, the lips, throat, and tongue, were much swollen, and very painful; and the stitches had cut themselves out. Fomentations were used, purgatives continued, and within a week 30 leeches employed at different times.

The swelling having subsided, the granulating surfaces of the wound were retained in contact by twisted sutures, and soon united, and he was dismissed 13th Dec., some motion at the fractured part being still perceptible, but with the teeth which had been loosened firmly fixed.

CASE III.—Fracture of lower jaw, complicated with wound on chin; no displacement.

Stephen A., aged 28. Nov. 17, 1841. Last night, while attempting to stop a waggon, which was running rapidly down an inclined plane, by thrusting a crow-bar between the spokes of its wheels, he was struck on the chin by the handle of the crow-bar; by which the jaw was fractured. The symphysis, and soft parts over it, are divided, but the wound does not communicate with the fracture.

There was not any displacement, and the wound in the integuments being united by suture, a bandage, to prevent motion of the jaw, constituted all the treatment required.

CASE IV.—Fracture of lower jaw by the explosion from a gun, into the mouth—laceration of uvula, mucous membrane of lips, cheeks, and pharynx—concussion?—death.

John R., aged 23, 1841. August 24th, 12 P.M. An hour ago, while holding a gun with the touch-hole near to a flame of gas, the muzzle in his mouth, and blowing to ascertain whether or not the touch-hole was obstructed, a part of the powder contained in the gun was blown out, ignited by the gas,

and communicating with the powder in the gun, he received the explosion, and it is said the wadding also, into his mouth. The lower jaw is found fractured a little to the left of symphysis, and the right fragment is drawn backwards, inwards, and downwards. The soft palate is lacerated, and separated on the left side to the extent of an inch. There are several small ragged wounds at the posterior part of the mouth, and on the inside of the lips. There is some sanguineous oozing from the mouth. Pulse 96.

On admission, the edges of the wound in the soft palate were placed in contact and retained by suture; the four-tailed bandage applied over the chin, and secured upon the head. This plan not answering, however, the fracture was put up, with the teeth received into a piece of grooved cork, a compress under the jaw, and the four-tailed bandage over it.

Next day the fragments were again found displaced; there was much swelling over the left angle of the jaw, face, and side of neck, and some crepitation from the presence of air in the soft tissues; there was also inability to swallow, and slight obstruction to respiration. Pulse 120, tolerably full.

To be bled to 16 ounces, and to inhale the vapour of hot water frequently.

On the 27th it is reported, that an hour after the visit yesterday, he became so weak, that a second bleeding, ordered conditionally, was not practised; he has repeatedly vomited the water which is conveyed into the stomach, by means of the syringe and tube, to allay his urgent thirst; he has been occasionally incoherent, and the right pupil is dilated and sluggish; pulse 150, very feeble.

Died at half-past 9 p.m., nearly three days after receipt of the injury.

Inspection, 40 hours after death.—The whole of the mucous surface of the pharynx is wanting, from behind the nose to the level of the fifth cervical vertebra. The membrane lining the larynx is of a bright red colour; some blood appears infiltrated into the substance of the scaleni and sterno-mastoidei muscles. No foreign body discovered in any part of the head or neck, and the brain was normal in appearance.

The cause of death in this case does not very satisfactorily appear from the

account of the inspection. I now think that it would have been proper to have examined the condition of the cervical vertebrae, and of their contents, and also the state of the organic nerves traversing the neck. The symptoms forbid the inference that concussion of brain had occurred to any prejudicial extent. There was no paralysis, which would have been present had there been considerable injury to the spine or maxilla; there were neither intense symptoms of laryngitis nor any strongly-marked appearances of that disease; and unless upon the supposition, somewhat a vague one, it must be confessed, that the organic nerves in the neck had suffered, or that their lesion and that of the highly sensitive pharynx had depressed and overcome the vital powers, I do not see how the fatal result can be explained.

The principal practical inferences deducible from the foregoing cases, are, that the state of parts varies greatly in fractures of the lower maxilla, and consequently, that similar treatment is not applicable in all instances.

Contrary to usual observation, the fractures in the cases detailed, all occurred at, or near, the symphysis, where, from the capability of making the extremity of one fragment press upon and support the other, adjustment is more easily preserved than when the injury exists in the ramus, or above the angle.

When the periosteum and muscular investments of the bone are not lacerated, there is little, if any, displacement; and supporting the teeth of the lower on those of the upper maxilla by bandage, and maintaining quietude, as in our third case, will always suffice.

Where the fracture passes in a direct transverse line through the bone, or where the two surfaces break roughly, and lock into each other, there is not in general much displacement; and the means above referred to will commonly prove sufficient, or if they do not, recourse can be had to the grooved piece of wood or cork, with or without a ligature of wire around two or more of the teeth. These means, accompanied with a compress shaped to the semicircle of the inside of the jaw, and placed below it, where, being pressed by the bandage, and throwing out the fragment, which may be displaced by the muscular

action, will in general be sufficient to effect all that we have in view.

It is in cases where the fracture is oblique, and the investments are torn, as in our fourth instance, that difficulties in maintaining apposition are met with. When such a fracture is situated at the symphysis, the genio-hyoidei, the genio-glossi, and digastric; when it exists at the angle of the jaw, the pterygoidei, temporalis, and masseter, cause displacement; and when in the ramus, the mylohyoidei and platysma, probably irritated by the sharp fragments, and acting strongly, cause the two portions to overlap, and one of them to be drawn within and below the other, as in the fourth case.

If, in such circumstances, the ligature of wire, the grooved cork, or both of these, with the compress under and within the circle of the maxilla, and pressure of the four-tailed bandage over it, do not retain the portions exactly, then the only resource with which I am acquainted, and which in such a case I think should be tried, is the apparatus described by Mr. Lonsdale, consisting of two metal plates, the one with a groove corresponding to the line of the teeth, the other with one receiving the inferior edge of the jaw, and the two plates attached by a screw, which permits them to be approached or separated at the will of the surgeon.

All the methods above mentioned, with the exception of Mr. Lonsdale's, I had tried unsuccessfully in the fourth case. The fracture was very oblique, and was no sooner reduced than it was again displaced; and it was my intention to have made use of Mr. Lonsdale's apparatus, which, though I have never seen it employed, is constructed on such principles as almost to ensure its efficiency.

ON HUMORALISM IN FEVER, INFLAMMATION, AND IRRITATION.

By T. WILKINSON KING, F.R.C.S.E.

(For the Medical Gazette.)

*Is local inflammation a cause or a concomitant of fever? Analysis of Louis. There are preparatory deteriorations of fevers in every various grade, as also of inflammation.**

THE opinion that local inflammation is a cause, and not a mere concomitant of

fever, seems to be too generally contended for. My own reflections have often been directed against the view as a positive or unlimited one. A reproof for inexperience in the matter, somewhat readily expressed by one of my compeers, has set me to reconsider some of the facts of the subject.

About the same day one urged to me that herpes labialis often causes a fever, and another, that in the same case, according to his experience, pneumonia was seriously to be anticipated. Now I imagine there is little doubt that the same general disturbance may induce a fever, attended with acute inflammatory acts, in any two or six organs of the body.

An old pupil, who made free use of my manuscripts to support what I have long taught—that the fever following local injury is nowise proportioned to the violence, but to the previous state of the blood—yet describes the *irritative* fever of operations, &c. as very often the effect of mere arachnitis.

I am still informed by able physicians, that it is common to see fever depending on inflammation of brain; but reverting to the errors of Broussais, Armstrong, Clutterbuck, and Louis, I fall back on a coarse kind of general induction (furnished by the broad facts in pathology), which, although requiring much to render it precise, is in my judgment sufficiently clear, and far better than the most definite mistake, for the regulation of daily practice.

It seems to me in a manner fatal to medical philosophy to treat of fever in the exclusive manner pursued by M. Louis. Surely the most indistinct or transitory appearance of maculæ should weigh very little in determining the specific nature of typhus. And what shall we conclude from the fact that very many organs may or may not be very variously affected in fever; and that its especial morbid anatomy is confined to some constant, though often very inconsiderable inflammation of the iliac patches, and to some occasional similar disease about the epiglottis after twenty-five days of feverish breathing and decline?

What does it add to the physiology of fever to exclude all cases under fifteen years of age, and above thirty?*

Journal, I would only observe, that they seemed to me to require this mode of procedure to extend and corroborate them.

* Between fifteen and a half, and thirty-nine; eight out of 140 were above thirty.

* If it should seem that the following view is a repetition of former papers on Irritation in this

										Mucous membrane white in 13 cases.
"	"	"	"	"	"	"	"	"	"	red " 20 " the extent varying.
"	"	"	"	"	"	"	"	"	"	grey " 9 "
"	"	"	"	"	"	"	"	"	"	of natural consistence in one-fourth of the cases.
"	"	"	"	"	"	"	"	"	"	softened in three-fourths of the cases more or less in degree and extent. Sometimes thickened.
"	"	"	"	"	"	"	"	"	"	ulcerated much or little in 14 of the cases.
"	"	"	"	"	"	"	"	"	"	lenticular crypts in 8 cases.
"	"	"	"	"	"	"	"	"	"	"plaques dures" in 4 cases.
Glands, mesenteric, corresponding to plaques, red, thickened, and soft, in all the cases.										
"	Mesocolic	"	"	"	"	"	"	"	"	"
"	Gastric sometimes	"	"	"	"	"	"	"	"	"
"	Hepatic twice	"	"	"	"	"	"	"	"	"
Spleen affected in all but 4, large, "often quadruple" and soft; always soft if very large; less affected after the 30th day.										
Some morbid states of the spleen are sequela, but such are rare.										
Liver softened in half of the cases, &c.										
Bile affected in most of the cases, and in excess.										
Gall bladder contained a pus, in three of the cases being thickened and inflamed.										
Kidnies generally healthy, but soft and tumid in a few.										
Heart softened in half of the cases, more or less, being thin and red and laceable, and containing dark blood.										
Aorta red and tender within, in all of the cases where the heart was affected.										
Epiglottis thickened and eroded in one-sixth of the cases; slightly covered with lymph in 2 cases.										
Larynx, false membranes in 3 cases.										
" a little ulcer in 1 case.										
Pleuræ, reddish serum, about $\frac{3}{4}$ in nearly half of the cases.										
Lungs, splenized or hepatized in two-thirds of the cases only, more or less.										

Now it is doubtless well to have a fixed distinction between the cases described by Louis and all others—it is even very essential to distinguish the differences in the cases he records, but it is first of immense importance to determine if these be specific with all their gradations, and if all ulterior grades be otherwise or oppositely specific, which I do not believe. Surely a little more of an active affection in head, chest, or belly, cannot be sufficient to characterize the case as a phlegmasia, and not fever.

The present state of opinions appears to be, that fever may arise from local injury, local inflammation, local poisoning, (becoming general), and from constitutional causes *idiopathically*?

Now we know that all kinds of transitory fever come and go, and leave no trace; and that others may or may not be attended early or late by local inflammation in any part of the body. Dr. S. Smith in 1830 justly distinguished serious fevers as having predominant local affections in the head, chest, or

belly; we should add, in the limbs also. Dr. Hodgkin much earlier hinted at humoral views, of which he has given a sketch in his Pathology of Mucous Membranes. I have before explained the basis of my own opinions (see Toothache, MED. GAZ., January 1842, and the Physiology of Angina and Asthma, MED. GAZ., 1841).

No one seems to contend for the existence of any one uniform cause of fever, and yet anything may, it would seem, be such a cause occasionally. It would almost appear as if the great alarm bell of the City could sound at times without a cause or from any cause, and yet that the greatest cause may often fail to excite its feeblest note. An eminent surgeon, spending a week out of town, was tempted, though seeming well, by a bottle of aperient on his mantel-shelf. Three or four days of feverishness followed. A somewhat delicate student travelled 100 miles on a frosty night upon a stage-coach without a great coat, and experienced little more than a few hours of fatigue. Now to say that the state-

ment of such facts is puerile, I freely allow; but on the other hand is it not true that such things do not have their due weight, meaning, and explanation, when sympathy and irritation, and sympathetic fever are under process of illustration even by "orthodox Humterians"?

Not to set down my own experience numerically, I would first, then, divide fevers into two series—those which leave the patient to all appearance as well as ever, and those which end fatally; (it is evident that a third set of cases remain, namely, those in which a settled disorganization, as amentia, or abscess, is left to exert its ulterior influence). It is most certain that the grades in the two series are about as numerous as the cases that occur; yet I offer no objection to the terms by which writers designate their classes and orders. Every distinction should be admitted to characterize the form of a local inflammation; but when we come to regard fever as a process, what is it but a train of *general* capillary disturbances more or less complete and extended? And what is inflammation but a course of *local* capillary acts? And what regulates the action of capillaries, locally or generally, so much or so directly as the blood sent to them, whether for nutrition or for secretion, for disorder or for repair.

Let us grant some effects of sympathy and of still more manifest nervous influences; but let us not deny heedlessly that the rise and course of fever may be universally of one kind—gradual deterioration of blood from all causes, and the convalescence a gradual restoration of the blood.

Some preparatory deterioration can alone account for the acute fever after common injuries;—loss of blood, cold, abstinence, rest, and physic, may add to the mischief. So in simpler fevers.

Some preparatory deteriorations are necessary to the production of pneumonia; and the patient's viscera, his bedroom, and his medicines, regulate the changes of his blood to death or to recovery. I would wish to define inflammations as altered nutritions—tumefactions, watery, fibrinous, bloody, purulent, softening, indurating, &c. Compounds of "ale" might express these bad, excessive, and deficient changes of nutrition.

Andral shows fairly that the blood

superabounds with fibrin in phlegmasia, and not in fevers; and no doubt the two opposite febrile conditions are marked enough, but without any kind of boundary. To establish typhus are we to exclude every thing else? If so, I contend that the exclusion of fatal local disorders of nutritions excludes all that is fatal, except a few cases which most resemble sudden poisonings of the blood.

In all countries, particular constitutions, with particular seasons and habits gradually fall into a state of disorder. Sooner or later, sporadically or epidemically, the national fever, with maculae, jaundice, or buboes, may affect them, (I do not deny contagion), and in the course of days sanguineous changes of nutrition may bring some vital organ to destruction, or the whole body to restoration, as if by excretory depositions.

It is not more repugnant to humoralism than to any other doctrine, that the national diet should determine the local changes of fever and of phlegmasia, or that climate and peculiar seasons should act in a like manner, or that certain influences should be most obnoxious in certain ages of life. It is not more true that one "*enfeeble his vital powers by over stimulations*," than that alcohol may deteriorate the blood, digestion, maturation, secretion, and depuration.

It is not surely very inconsistent that impeded renal secretion should alter the character of inflammation and fever, or that a fixed degree of disorganization in any organ should produce similar effects; but it is an inconsistency, I think, to say that the fever, or phlegmasia, which is simply, though necessarily, modified by any old disorganization, is therefore not a fever or a phlegmasia.

In a protracted case of violent tertian, I once observed to an old clinical teacher of mine, there is nothing strikes me so remarkably in this patient as the copious urinary sediment after the attack. The answer was: why, this is only an usual symptom of the disease: my own mind occupied itself with the inquiry—is it merely a depuration of the blood after the disorder, or is it more connected with the cause of the disease?

Hectic is an extreme case of susceptibility to the external impressions of cold, food, or medicines; and it is by the judicious and careful exclusion of

fresh disturbances, together with the most cautious supply of invigorating remedies, that the power of resisting outward agencies may increase, and vigour by degrees be regained. No less certain is it, that excessive heat may add to the debility of hectic, than that moisture and warmth increase the discharge from an open fracture. Cold certainly induces a hectic fit, and excretions attend its decline.

It may very well shock some physicians to talk of acute peritonitis as one proper attendant on fever, yet the ordinary distinction of cases may be still more erroneous. The rapid attack which obliterates the serous cavity with cellular membrane, is in a manner harmless, while the fever case, which ends quite unexpectedly, with a pint of pus and bloody water in the belly, may never have been suspected to have been inflammation at all. The sympathies of the two cases are different; for the inflammations or deposits from the blood occurring elsewhere are peculiar in each case. The inflammatory changes proper to what we call fever, when fatal, are scanty, watery, and softening, in any or every part of the body. Phlebitis, and hepatic abscess after injury, or not, are but two modes of inflammation in a fevered body*. The changes may occur in several parts of the body pretty simultaneously, but morbid anatomy teaches us, that whether fibrinous, gangrenous, watery, or purulent, the only difference which several depôts present in the same body depends on the age of the product, or on the state of the constitution at the moment of producing it. We do not find serum in one lung, and fibrin in the other; bloody effusions in the belly, and purulent in the chest. The terms "hæmorrhagic diathesis," "inflammatory disposition," and "tendency to deposit pus," offend no one, and morbid anatomy greatly extends the application of such expressions. If a stump heals well, and the patient take cold, and have a solid pneumonia, it is not more wonderful than that fever, with an ill-conditioned wound, should introduce suppurations or itises in four

or five distinct parts of the body. I think thus we may understand why there should be successive periods of recovery and relapse in the course of such cases even to death or recovery.

On the whole, we conceive that it is nearer to the truth to call all that fever which is allied to it. Thus we find clear room to arrange the deteriorated humoral capillary acts (by which I mean processes) which attend fever in somewhat of a natural series. Some are deficient or atrophic, some are excessive in the way of secretion or nutrition, and all are marked by some degree of deterioration up to a certain moment, after which it would seem that secretion, assimilation, and nutrition, may be gradually restored to their fullest healthy action; or disorganization ensues, which directly or ultimately proves fatal.

If ague be fever, is not that fever which, every ten or twenty days after fresh incidental deteriorations of the body, introduces renewed inflammation of strumous parts, or of catarrhal membranes? Simple acute ophthalmia and fever occur in one *predisposed*, while equal external causes applied to an entire regiment leave it with sound eyes, or rather with here and there one man disordered after a peculiar manner—more or less feverish or inflammatory—having any one or more organs inflamed or altered in a certain especial way, according to the state of his blood, and the efficiency of his blood-making and blood-cleansing organs.

I presume it to be very different from current opinions to regard fever as but partially modified by local inflammations; and yet even this scarcely seems a sufficiently exact expression without amplification.

The diathesis and deteriorations being given, and the consequent form of fever, and also the seat and character of local inflammation, being settled by the same causes as the fever, we may well consider what effects result from pains, and from arrested or impeded function, in any one organ, nervous, physical, or humoral. Ischuria may cause serous inflammations, diarrhoea, or emesis, without sympathy. Paraplegia may induce various defective secretions and inflammations through want of abdominal support, want of motion, &c.

It is very little to say that I have

* Visible pus in a vein or lymphatic is a positive proof that the circulation of the vessel has been long arrested. The absorption of pus to mingle with thirty pounds of blood, and yet be visible bodily in the heart, would be absorption with a vengeance—about equal to metastasis of the walls of an abscess!

been long seeking a simple case of fatal fever, and it may not seem to many very significant to observe that, with much knowledge of morbid anatomy, I know nothing of the changes peculiar to fever besides those which characterize a certain type of inflammations; that I know of no one organ, or set of organs, being affected, save the universal changes in the capillary system and its directing blood.

Every age, sex, and class, local climate, and season, has its peculiar febrile disorders; all modes of life, and remarkably all changes of mode, have theirs. Take simple cases of the resolution of fever and phlegmasia—take the worst cases of fever, and of various inflammations, that recover—and what do they offer in proof that the phenomena attendant on two-thirds of the cases of “affection typhoid” is more feverish than heat of skin and massive hepatization of lung without typhus? Is it not more truth-like that all the grades of pneumonia, or icteric fever, are local effects of sanguineous deterioration? What shall we say of such cases as the following, the like of which almost all seem determined to hold as mere local irritation? An old gentleman had calculus, and it was not deemed desirable to operate on him, as he suffered very little. “He was a convivial man, dining a great deal in society, as if he had no ailment. Every now and then he was suddenly seized with the usual symptoms of stone in the bladder, and very severe ones too: he then (says Sir B. Brodie) sent for me. I kept him in the horizontal posture, prescribed him an opiate clyster, and in the course of a few days, sometimes sooner, sometimes later, the attack subsided; he was again at his ease, and able to return to his usual habits. I had thus been occasionally in attendance on him for three or four years, when he was seized with a severe cold, which ended in a pleurisy, of which he died. On examining the body, I found the stone embedded in a cyst near the fundus of the bladder. The cyst was formed in this case, not by the protrusion of the mucous membrane between the muscular fibres, but by a dilatation of both tunics of the bladder, the muscular as well as the mucous. The stone was not, it seemed, so closely embraced by the cyst as to prevent it occasionally slipping out of it: I sus-

pect that this actually happened, and that it was when the stone lay in the cyst that the patient was free from the usual symptoms of calculus, and that his sufferings took place when the stone escaped from it into the general cavity of the bladder.” These details may, by license, be used to illustrate the author’s opinion; but we know that the relapses of cystitis and pain occur without the existence of pouches, and even without stone. The patient’s habits, exposure, and wine, prepared for a feverish relapse; care and time obviated the inflammatory diathesis; at length, an overwhelming seizure came. Is it not very plain that the ever-varying sensibility of the bladder to the presence of stone depends, first of all, on the state of nutrition which it derives from the blood? A stone grasped in the summit of the bladder, or loose at its base, may give no pain for months. Well-nourished heels do not easily blister. Irritable bladder varies with the health of the blood, and a watchful eye discovers commensurate signs of fever, not the consequences of the local state but of the general disorder concomitant, which any part already subject to disorder may have to bear the brunt of.

If it is again necessary to excuse the method I pursue, I would claim some consideration on the score of weakness, especially considering the array of opinions against these views. My “Views of the First General Laws of Medicine,” &c.* and of “Variable Disorders,”† are, I think, reasonably carried out by the present.

36, Bedford Square.

THE OPERATION OF LITHOTOMY;

A MODERN CHESelden!

(For the London Medical Gazette.)

IN the eighteenth century, a surgeon named William Cheselden, who signed himself “Surgeon to his Majesty’s Royal Hospital at Chelsea,” and who, moreover, there is every reason to believe was surgeon to St. Thomas’s Hospital, London, wrote as follows: “What success I have had in private practice I have kept no account of, because I had no intention to publish it, that not

* London, Churchill, 1840.

† Guy’s Hospital Reports, No. 11.

being sufficiently witnessed. Publicly, in St. Thomas's Hospital, I have cut two hundred and thirteen; of the first fifty only three died; of the second fifty, three; of the third fifty, eight; and of the last sixty-three, six;" and at the close of his interesting paper on the subject says, "If I have any reputation in this way I have earned it dearly, for no one ever endured more anxiety and sickness before an operation, yet from the time I began to operate, all uneasiness ceased; and if I have had better success than others, I do not impute it to more knowledge, but to the happiness of a mind that was never ruffled or disconcerted, and a hand that never trembled during any operation."

In the nineteenth century, one who writes himself down "William Keith, M.D. Junior Surgeon to the Royal Infirmary, Aberdeen," states* that of "nineteen cases operated on by lithotomy, aged from fifty to seventy-eight, only one died," and therefore he "trusts he has a sufficient apology for coming before the profession with a detailed statement of a mode of practice that has been crowned with such signal success." Dr. Keith, too, modestly "refrains from contrasting the above results with the recorded experience of others at like ages, lest it should seem invidious," although, inadvertently perhaps, he reminds us that "the mean mortality in England is one in seven and one-fifth; that in France between a fifth and sixth of all who undergo the operation are lost; that in England beyond the age of fifty, the rate of mortality rises to one in four or five, while in France, on the authority of the most eminent French surgeons, it reaches one in every two or three." "Considerable interest must therefore," says Dr. Keith, "attach to a mode of operating and plan of treatment that has led to such results" as have occurred in his own practice.

We confess that we were somewhat anxious to learn "the mode of operating and plan of treatment," and therefore, although with sundry misgivings on the subject, looked eagerly for the promised account. We read it, and feel both pleased and disappointed: pleased with the full appreciation which the author displays of the most important

features of the operation; and disappointed at the vein of egotism, and even occasional worse taste, which pervades the whole paper*. We have looked in vain for any striking novelty either in the "mode of operating" or "plan of treatment": what is good has been known, expatiated upon, and held practically in view, by many others, and some that is new is of questionable character.

The author has cut his subject into eight different sections, through which we shall endeavour to follow him with a brevity fitted to our own pages.

1st. "*Of the preparation necessary before subjecting a patient to lithotomy.*" Dr. Keith advocates a preliminary treatment, and recommends rest, alteratives, tonics, specifics for allaying irritations of the affected organs, and such other means as a scientific professional knowledge would at once point out as advisable in all cases when an important operation is required, and where delay would not be productive of harm. He recommends the abstraction of blood from the arm, or by leeches over the pubes, in persons between 50 and 55, who are fat and florid, and also after the latter practice a "succession of medium-sized blisters over the region of the bladder." To the blood-letting we do not object, but if counter-irritation should be deemed advisable, the cantharides ought, in our opinion, to be used with some caution; a strangury would add greatly to the patient's sufferings. Dr. Keith imagines that it is almost essential to the success of lithotomy, that the surgeon should secure the "well-grounded" confidence of the sufferer, and thinks that the period employed in preliminary treatment may be advantageously used by the practitioner for this purpose. A list is given showing the number of days after admission which each out of 23 cases has been subjected to. The periods vary from four days to seventy-four: in few cases are the dates alike, yet an average is struck showing 25.1 days on the aggregate amount. Three are cut on the 14th day; two on the 24th; three on the 25th; and all the rest on different days. We have been puzzled as to any practical deduction to be drawn from the above arrangement, and fancy that the calculation has as

* Edinburgh Medical and Surgical Journal for January and April, 1844.

* Practical Observations on the Lateral Operation of Lithotomy. Edinburgh Medical and Surgical Journal, April 1844.

much useful reference to lithotomy, as if the number of miles each patient had walked from his house to the hospital had been counted up, and the average given.

2d. *The instruments* recommended are a staff, knife, probe-pointed bistoury, blunted gorget, slit probe, and sharp hook. The staff and knives differ in no material respect from those recommended by other good authorities, and the probe and hook are part of the apparatus which a surgeon generally has at hand when setting about any cutting operation. We agree with Dr. Keith in his opinion that Cheselden's forceps have never been improved upon (except in lining their chaps with linen), but object to the gorget which he uses, as being altogether unnecessary, dangerous, and just that part of Cheselden's apparatus which may with propriety be omitted: "its left edge is quite rounded, the other ground to an edge and then blunted with a file," and we shall see immediately to what use it is applied.

3d. *The first incision* our author places very low in the perineum. He commences close to the raphe, behind the swell of the bulb, one inch in front of the anus, and proceeds about three inches outwards and backwards, keeping rather closer to the tuberosity of the ischium than to the anus. He objects strongly to any interference nearer the scrotum; pointing out what he considers the danger of wounding the artery of the bulb, and of cutting down on the symphysis pubis instead of the lower opening of the pelvis. In our opinion far too much importance is placed on the particular seat and line of the incision recommended by Dr. Keith, and we do not by any means assent to his arguments for keeping the external wound so low. The wound in the skin is made with the double intention of facilitating the access to the deep-seated parts, and permitting the ready escape of the stone. Now we imagine, that by keeping so near the hip, the operator is further from the parts which should be divided than if he were passing a little nearer the pubes, and we also think that undivided skin in the fore part of the perineum is likely to prevent the free use of the forceps, both in catching the stone and in its extraction. We advocate a high incision in the perineum, because it

permits a ready approach to those parts which all admit are implicated in the operation, viz. the membranous portion of the urethra, prostate gland, and that part of the bladder covered by this organ, and we maintain that while it greatly facilitates all the steps of the operation—provided it be carried downwards to a full and proper extent—there need be no such dangers incurred as those which Dr. Keith refers to: neither need the artery of the bulb be wounded, nor is it a necessary consequence that the future stages of the proceedings are all conducted high between the rami of the pubes. The free division of the skin over the bulb does not of necessity involve that part itself, and we maintain that the very parts which our operator aims at cutting will be reached with additional freedom by this preliminary step. To the best of our recollection all lithotomists have carried their cutting instruments into the bladder in a horizontal direction, some in a downward line—especially at the neck of the viscus, and considering the relative position and attitude of the patient and operator, the latter could not carry his hand and instruments in any other direction without inconvenience. In Dr. Keith's own drawing representing his lines of incision, we fancy, supposing that the operator is seated in front of the perineum, that the hands are in a most awkward direction; they would be so were the operator on his knees even. It is evident, too, that to complete the incision, whether with the knife or bistoury, the attitude must be much the same, else the upper part of the wound will impede any attempt to carry the cutting instrument nearly parallel with the staff. But to be brief, Dr. Keith's own sketch furnishes the clearest argument against his own external incision; for it is evident that it would be impossible to seize with the forceps the stone in the lower part of the bladder without applying great stretching force either to the skin or to those parts which attach the neck of the bladder to the pubes. We have never looked upon Sir Charles Bell as a high authority on the subject of lithotomy, yet we do not agree with Dr. Keith in his criticisms on that surgeon's first incision: on the contrary we think Sir Charles's much to be preferred to his own, both in respect of its

height in the perineum, as also its greater proximity to the mesial line; and besides, we maintain that it makes a nearer "approach to the outlet provided by an all-wise Creator in the other sex," than that which he advocates towards the hip. Look at the perineum as the operator sees it before he applies the knife! Supposing he was asked to place his finger on that part of the surface nearest to the neck of the bladder, would he not lay it on the mesial line a little in front of the anus? Assuredly he would not place it upon that prominence which is always conspicuous (especially in the fat subject) midway between the anus and tuber ischii. Dr. Keith, in our estimation, entertains an absurd dread of wounding the artery of the bulb: we ourselves have no such fear; we doubt if there be the danger attending its division which many have asserted, and, moreover, we say that the operation is dangerously executed when the knife is thrust in such a direction as to implicate this vessel. We cannot but fancy that an incision near the mesial line, while it is evidently nearer the neck of the bladder, permits of greater dilatation than that towards the tuberosity of the ischium; and that, in following the directions of Dr. Keith, there is more danger of coming in contact with the pudic artery itself than of wounding the artery of the bulb in the mode of proceeding followed by most of our best operators. We agree with our author in his estimate of the dangers of the operation when performed high in the perineum; beyond a doubt, much havoc has been produced by this improper proceeding: we trust, however, that, in expressing our dissent from his low external wound, and recommending that it should be made much higher, we shall not be supposed to inculcate that the remaining steps of the operation should also be conducted nearer the angle of the pubes. We perfectly coincide with Dr. Keith as to the locality and extent of his further incisions; but as he has, in a manner, challenged attention to his first incision as being superlatively good, we have deemed it right to state our opinion to the contrary; and we must say, in addition, that he has not sufficiently appreciated the distinction between beginning the external wound high in the perineum, and continuing

the future steps of the operation in the same position. He has not done Sir Charles Bell justice on this score; for that surgeon was well aware of the danger of being too near the pubes, and expressly cautions us to avoid such a mistake.

4th. *The second incision* is, in our opinion, just where it should be; but we take leave to doubt if the author ever made one of the kind in the way he recommends. First, the membranous portion of the urethra is opened with the knife used to begin the operation; then the beak of a probe-pointed bistoury is placed in the groove of the staff, and the blade is carried onward so as to make a slight notch in the apex of the prostate; thereafter a gorget, with its cutting edge purposely blunted with a file, is thrust towards the bladder in such a manner as to divide an additional portion of the gland in a line continuous with the notch already made with the bistoury. We ourselves doubt the possibility of cutting the prostate gland with an instrument which has been intentionally made blunt; and much as we dislike the cutting gorget of Hawkins, we should certainly prefer it to the blunt instrument of Dr. Keith: nor will it alter our opinion if we are referred to that gentleman's success in its use, as we might easily shew, by reference to Mr. Green's practice, and that of others of acknowledged skill who have used the cutting gorget, an amount of success far beyond that which has yet been attained in the Aberdeen Infirmary. When we reflect on the well-authenticated casualties which have followed the thrust with the sharp-edged weapon, we feel inclined to congratulate Dr. Keith that there has been no getting between the bladder and rectum, nor between the bladder and pubes; no awkward slipping, plunging, or perforating, in his hands; and we say fervently, God save all who are to be treated with the blunt gorget in future! Our author has here copied the most useless feature in Cheselden's operation; but instead of leaving bad alone, he has made bad worse. So far as we can perceive, Cheselden used his blunt gorget solely as a conductor: it was slipped by him, easily and without force, into the bladder after he had made his incision into the prostate, and the forceps were slid along its

concave surface. We have always thought that the substitution of the forefinger of the left hand, as used by some of our best modern operators, has been a great improvement on Cheselden's proceeding. If dilatation be thought necessary whilst entering the bladder, we hold that the finger is to be preferred to the blunt weapon of Dr. Keith; and in the majority of cases it is additionally useful in detecting the exact seat of the stone, and in placing it in a favourable position to be seized readily with the forceps. It must be remarked that Dr. Keith wisely recommends the gorget to be passed onwards "neither with force nor in haste, but by a firm and steady movement, guarding against the possibilities of a plunge," &c. &c.; and, moreover, that with sundry other good precepts, he warns all beginners to trust to "a calm collectedness of mind ready for any emergency;" yet withal we should shudder to see a tyro attempt to cut the prostate with an instrument specially blunted for the occasion. We shall expect, in due time, some statistics of amputations done by the same dexterous hand, accompanied by a drawing of the amputating knife, having one edge "quite rounded, the other ground to an edge, and then blunted with a file." The practice might be termed the Northern Paradox!

We have already hinted at the danger of coming in contact with the common pudic artery in the peculiar external incision recommended by Dr. Keith, and feel strengthened in our opinion by what he states with reference to the deeper part of the wound. After the bistoury (which by the by really has a cutting edge) has been thrust into the bladder, "I usually," says he, "in withdrawing it, bring it out of the prostate, and take a sweep along the lower angle of the wound out to the very skin." Now when it is considered that by the natural gaping of the wound, as also the pressure with the knife, the margin of the *very skin* must lie almost over the tuber ischii, we imagine that we have not in any way overrated the danger to the common pudic artery. Dr. Keith, we think, has been fortunate in avoiding it.

We regret that our limits will not permit us to follow Dr. Keith much

further, but having given free expression to our feeling, where we disagree, we feel no less bound to state that the tenets and practice inculcated by him on other points than those to which we have called attention, are such as meet with our general approbation. In his advocacy of gradual dilatation of the neck of the bladder in preference to the free incision, we heartily concur: his directions to avoid bruising the soft parts we think most excellent: he overrates, in our opinion, the dangers from bleeding, but has clearly shewn that the most certain preventive of infiltration of urine is to limit the incisions within the bounds of the prostate. His observations on wounds of the rectum are especially worthy of notice, and we join in his opinion that the accident, when unfortunately it does occur, is of far less moment than it has usually been deemed. We think with him and all other authorities that great care should be taken to avoid this part, but have our suspicions that it is more frequently wounded than lithotomists have admitted! The effects of such a wound may be troublesome, but the additional danger from it (if there be any at all) must be of the most trifling kind.

On the treatment after the operation. Dr. Keith exhibits much professional judgment and skill. Perhaps this section, and that on preparatory means, are the most commendable of all he has written, and he has done well in showing that much is required on the part of the surgeon besides the extraction of the stone. His directions for the after-treatment are most admirable.

And here we wish we could take leave of Dr. Keith for the present, with a hope that his success may continue, but we feel bound to follow him yet a little further. "One other principle," says he, "that has exercised great influence over my success, I must announce before closing. Believing, as I firmly do, that the issues of life are wholly in God's hands, I never fail urgently to implore his presence and blessing on every operation. From my bended knees I approach the operating-table, the immediate effect of which is to impart to me a calmness that nothing can ruffle, a self-possession that has never been disconcerted—(and occurrences have happened that might have embarrassed any one)—a steadiness of hand, and

fertility of resource, that I thankfully acknowledge as gifts from God, while the final results have come out only such as could issue where the blessing of the Almighty descends."

This "other principle," we make no doubt, is applied solely with reference to the safety of a fellow-creature about to undergo a dangerous operation; it would be unfair to suppose that Dr. Keith has a greater desire for personal *éclat* resulting from success than other surgeons, and it is but reasonable to conclude that he gives all his other patients similarly circumstanced the benefit of this feature of his practice. In operations for hernia, for aneurism, for the removal of tumors, in amputations, &c. &c., we fancy that life is in as imminent peril as in the instance of lithotomy, and it is beautiful to contemplate this blending of the most sincere acts of devotion with the consummation of skill in the healing art. The sacred character of the proceeding places it beyond and above all criticism; yet we may doubt the good taste of this ostentatious display of piety on the part of a surgeon. We hold it as a maxim, that in this Christian country every surgeon is deeply imbued with reverence towards the Divine Author of our being, and we do not hesitate to express our conviction that many who may possibly not have had the same success as Dr. Keith, have nevertheless had as devout a feeling of reliance on the blessing of God. We have no objection to Dr. Keith taking to his "bended knees" before he performs his operations, but the published parade of his sanctity is, in our opinion, wretchedly misplaced. We could not but contrast the modesty with which the Cheselden alludes to his success—as exemplified in the extract with which we have commenced this article—with that of the modern Aberdeenshire lithotomist. Dr. Keith certainly, after enumerating all his good qualities—such as "self-possession," "steadiness of hand," "fertility of resource," &c., admits them all to be "gifts from God," and we are led to believe, too, that these gifts were not greater than the exigencies demanded, for we are expressly told that "occurrences happened which might have embarrassed any one." We have wondered what those "occurrences" were, for we cannot see that there was anything much out of the

ordinary course in the cases alluded to. The heaviest stone seems to have been twenty-eight drachms, the average weight of all, eight drachms and fourteen grains; and, so far as we can perceive,—saving the author's own peculiar style of operating—there has been nothing extraordinary in any single case.

We suppose it is a weakness in our character that we should always look with suspicion on any one who professes greater sanctity than his neighbours, and we in a manner flatter ourselves that it has been our "gift from God" to judge of things as we find them. Out of nineteen cases of certain ages, Dr. Keith has lost only one after lithotomy, and this he makes conspicuously clear; yet out of twenty-three cases he lost two! The success is most creditable, yet it is not by any means equal to what has occurred in the practice of other surgeons. If we mistake not, a northern contemporary, Mr. Chrichton, of Dundee, cut his first two and twenty cases with success; and need we remind our readers of what happened with Blizard, Martineau, and others? On turning to Dr. Keith's cases, we find that of the first five cases he lost one, of the next nine he lost another, and that the other nine have recovered: yet is there anything extraordinary in all this? The late Mr. Lynn, having performed lithotomy five and twenty times successively without losing a patient, vaunted himself on his success; he thought he had discovered the "secret of lithotomy," but he was known to have said in after years that "God had punished him for his presumption, for the very next four that he cut all died." We all know the extraordinary success which Martineau enjoyed in one period of his practice,—he having operated in eighty cases, with the loss of only two; and we know also that the most distinguished practical surgeon of the day in Scotland*, who has had far more ample experience than Dr. Keith, of Aberdeen, has no reason to plume himself on his high average of success; yet here we have a junior surgeon, who happens to have lost two cases out of twenty-three—being all that he has operated on by lithotomy—boasting of his extraordinary success, and writing of

* *Fide* Syme, in London and Edinburgh Medical Monthly Journal, for December, 1842.

the operation as if it had never been practised before, either to the like extent, or with such results! This reminds us of an old village practitioner who used to congratulate himself on his success in reducing strangulated hernia; "he had never used the knife, whatever Astley Cooper, Dupuytren, and others, had done;" and we have a recollection of another genius in surgery who lost his second case of amputation, but congratulated himself that it had been the *only* unsuccessful case of *all* he had treated! This boasting of success is always suspicious, and Dr. Keith will please excuse us admitting any superior peculiarity of system until he can show numbers and success equal to those that are already perfectly familiar to every well-educated surgeon.

NOTES OF A SECOND MESMERIC EXHIBITION.

(For the London Medical Gazette.)

THIS was what was called a *private sitting*, being held (July 19th) at the house of the physician who now reports it, and who reported the former. On this occasion, M. Marcillet, of course, received his usual fee of five guineas for the performance. The company consisted in all of less than twenty. All present were medical gentlemen except *five*, two of the five being of the respective ages of fifteen and sixteen*.

It being well known that the mesmerisers are in the habit of attributing failures, when they occur, to the uncooperative or hostile interference of the disbelievers, it was predetermined that on the present occasion MM. Marcillet and Alexis should not only have every courtesy shewn them, but should not be interfered with in any way, except in so far as was absolutely necessary to ensure anything like accuracy in observing the proceedings. And this determination was rigidly acted on throughout; M. M. being given distinctly to understand that he

was to follow his own plans, the company being simply spectators, unless called on by M. M. himself, to assist him or his ward. One of the company agreed to take notes of the proceedings in short-hand. This gentleman placed himself in a corner of the room at some distance from Alexis, in order that he might not attract the attention of the latter. I thought he remained unnoticed, but it was afterwards found that he was noticed by M. M., and his presence was urged as a grievance by M. M. *but not until after the occurrence of many failures.* It is most certain that the process of note-taking was conducted with the greatest calmness and reserve, so as to be unnoticed by almost every one in the room. This precaution was purposely taken in order to avoid giving offence to M. Marcillet, or interfere in any way with the proceedings of Alexis. It was arranged that, during certain of the experiments, the minutiae of which the short-hand writer could not distinctly see, another of the company should quietly communicate the facts to him.

About nine o'clock, M. M. proceeded to magnetise Alexis by sitting down before him, and steadfastly staring at his countenance. In the course of five minutes, or less, Alexis began to yawn and stretch, and immediately afterwards appeared to fall asleep. After a few further manoeuvres, M. M. considered him in a proper condition for action. He had previously prepared the apparatus for bandaging the eyes, but when this operation was going to be set about, Alexis declared his intention not to be bandaged. This was, of course, immediately complied with, without any reason being asked or given; and on Alexis proposing to play cards, a new pack was laid on the table and a gentleman of the company selected to play with him, as being known to Alexis, and considered by him and M. M. as favourable at least to mesmerism, if not a full believer in it.

I. The game was to be *Ecarté*.

a. Alexis took the pack, threw out the superfluous cards, and the game proceeded in the usual manner—the cards being dealt in the usual manner, sometimes by Alexis, and played with their faces upwards.

b. After a hand or two thus played, Alexis proposed to continue the game

* It is a minute and not very important circumstance, yet one worth mentioning, as showing as well on what small matters these exhibitors glorify themselves, as how their asseverations require being checked by calmer observation, that on this occasion M. Marcillet boasted not a little of the wonderful perspicacity of Alexis, in finding out, and telling him (M. Marcillet) that all the party were medical men (*médecins*) except two.

with a partition, or skreen, placed between him and his partner. The skreen used was a music-book (11 inches high by 14 wide) supported at the back by a small round sofa-cushion. Several hands were thus played, Alexis playing his cards down on his own side of the partition, or handing them over it, or round the end of it, and his partner laying his cards down on his side of the partition. Although the skreen was too low to prevent all possibility of vision, except when the cards of his adversary were kept very close to the cushion (which was on the adversary's side), and although they were not always kept thus close, still, as it cannot be proved that Alexis did see any of his opponent's cards, little or no stress is laid on this circumstance; the fact is merely mentioned historically, and as a hint for future experimenters.

The following is the account of this part of the performance from the notes of the gentleman who took them at the time.

"First game.—Alexis made a mistake in commencing the first hand, by desiring his opponent to play a *spade*, and he stated that his opponent had *four trumps* in his hand when he had *not one*. In the second hand, Alexis said that his opponent had *the ten*, which he had not; but he stated, also, that he had *two trumps*, which was correct; and also that he had *the seven*, which again was correct. In the third hand he was again mistaken in regard to the *trump card*, which he said was a *diamond*, when it was a *spade*; but although he was wrong in regard to the trumps, the cards afterwards fell as he had previously said they would fall. In the next hand the trump turned up he said was a *heart*, when it was a *spade*. He then asked for *five cards*, when he only required *three*. In the next hand Alexis was correct in statements *four times*, but was *wrong in three*.

"Second game.—In commencing the next game, Alexis was mistaken in the *trump*, and also in the *number of cards wanted*; and, on the whole hand, he was *twice correct*, and *twice in error*. In the second hand the cards were played with *their faces downwards*, when Alexis was again mistaken in the *trump*. In the third hand he was mistaken in the *number of cards wanted*, and he stated he had played a *red card* when

he had played a *black one*. He now threw up his hand, on the supposition that his opponent had the best cards, when, in fact, he himself had the means of winning the game, having the odd trick in his own hand."

Giving my own general impression of the results of the card-playing and card-seeing, I should say that there was very partial success, and a vast number of failures. The somnambulist sometimes played tolerably well; sometimes he named the number of cards wanted accurately; sometimes he was right as to trumps; but in all these respects he was much oftener wrong than right. In giving the names of cards placed behind the skreen, he over and over again not only mistook clubs for spades, and hearts for diamonds, but he mistook the cards of different colours, and even the court and plain cards of different colours, one for another. He sometimes fancied his opponent had a very good hand when he had a bad one, and *vice versa*. He sometimes followed suit, and sometimes he did not. In a word, his performance seemed decidedly better than what might be expected of a blind man, yet far short of what we had a right to expect from one who professes to see through opaque bodies. Indeed, his guesses as to the cards turned up behind the skreen were hardly more prosperous than mere random guesses might be expected to be, when we consider that there was only three to one against any one naming the right colour, and not a very vast odds (I do not know how many) against naming the right card, as all the small cards up to the sevens inclusive are thrown out of the pack.

II. Upon throwing up his cards, Alexis remained for some time in his chair, with M. M. seated by his side encouraging and condoling with him, while the company were seated or standing round the room, conversing quietly together, not at all interfering with the proceedings of the performers, and carefully keeping their opinions as to the past proceedings from the ears of M. M. and A. After a considerable time we were informed that Alexis was prepared to exercise his faculty of *clairvoyance* by reading certain words or sentences *through the pages of a book*, or through several folds of clean paper placed on an

opened page. The latter being proposed by M. Marcillet himself, three sheets of writing paper were placed open (that is, three leaves) across the two pages of a small book opened about the middle. The book was opened at random by myself, and the paper placed on pages without their being seen by Alexis or myself. The book was a small square duodecimo in French (Dr. De Carro's *Almanach de Carlsbad*) which I feel assured was not seen previously in the house by Alexis.*

a. After poring for a considerable time over the white paper spread on the book, with his hand pressing it in different parts, and his face pretty closely approximated to it, like a short-sighted person, he fixed on a point about the centre of the right-hand page, and spoke the words "*de France*," indicating the spot beneath which these words, he said, lay. I was particular in making him indicate the *exact spot*, and I also made him say whether or not the words (which he also wrote on the paper) were on the page *immediately* below the superimposed writing paper. He said *they were on this page*; and that both he and M. Marcillet expected to find them there appeared evident to me, from the obvious concern expressed by them when the paper was removed. The page (p. 77 of the book) immediately beneath the sheets of paper, was two-thirds *blank*, there being only seven lines of print at the top of it; and on the exact spot which Alexis fixed on, there was a small black line or mark, such as printers are accustomed to place at the end of a chapter,—which this was.

Although I regarded this as a complete failure, and it seemed at first to be so considered by MM. M. and A., they immediately shifted their ground, and said it sufficed if the words were found *anywhere* opposite to the indicated spot. They were, according to our plan, humoured in this, and search was made for the words in question. After turning over some leaves, and the exact words not being found, the performers at length seized on the word "*souffrance*," which was found on the leaf next to the blank one, (p. 79) in

the third line below the level of the spot fixed on by Alexis, and about half an inch to one side of it.

I cannot say how many pages were turned over in searching for the *clear-seen* words, but we certainly did turn over several, both at this time and on the occasion of the next experiment; and it is to be remembered, that while Alexis and myself were doing so (or rather while he was doing so, and I was trying what I could, without giving offence, to prevent him,) M. Marcillet was standing over us, and without restriction, eagerly examining the pages also. These facts, of course, utterly vitiate the succeeding experiments on the same book, as there was a *possibility*, at least, of their seeing words in other pages; and it will hardly be denied that there was an *extreme probability* that they did so. However, on the principle of letting the experimenters have their own way, under our close observation, we proceeded to further trials on the same book.

b. The paper was again placed by me on the book opened at random. It happened to be at page 98. On this occasion Alexis did not fix on words, but selected a point at the upper left-hand corner of the page, and said the page began with an *aline*a (a new paragraph, where the print was *set in* to the extent of a couple of letters). He distinctly said the page *began* with this *aline*a, and I marked the spot on and through the paper by strong pressure with my nail. On removing the sheet of paper, it was found that the page did *not* begin with an *aline*a, and that the spot indicated by Alexis was altogether above the commencement of the print. There was, however, an *aline*a or new paragraph, commencing with the *third line* of the page, and this was immediately seized on by MM. M. and A. as the thing seen and indicated. It was denied by M. Marcillet and Alexis that Alexis had said the *aline*a began the page, and the existing *aline*a was considered by them as sufficiently near the spot marked, to make the experiment perfectly successful! It is to be remarked that the pages of this book only contained twenty-two lines, and the paragraphs were very numerous throughout. In the very page in question, there were two other paragraphs. Of course it was perfectly easy for Alexis to observe, during the search for

* Even this, however, was *possible*, as this book was lying on a table in the back drawing-room in which Alexis remained a short time by himself, previously to being magnetised.

the words in the former experiment, this disposition of the print.

c. The paper was once more placed further on (p. 133), and after a short time Alexis announced that he saw a certain word, which he was requested to write down exactly over the spot where it was to be found. He did so, writing the word, (which, like the words "*de France*," still remains on the paper) "*Mülburn*," with a dieresis over the u.

On this occasion I don't think it was stated by Alexis that the word was certainly to be found on the page immediately below the paper, and consequently we allowed him to turn over the pages and look for it. After some time, neither he nor I being able to find the word, and it being regarded by me as of no real moment even if it was found (the experiment being vitiated by the previous leaf-turning), I shut the book, wishing that we should proceed to some other experiment. Seeing that there was disappointment and some dissatisfaction expressed by M. Marcillet at my conduct, I said, "I have no doubt the word is in the book;" thinking this almost certain, as the book was on the waters of Carlsbad.* Accordingly, I gave the book up into their own hands; and after a considerable search, not this word exactly, but one very like it, and one which, under ordinary circumstances, would be admitted to be the same, only misspelt—was found—viz. "*Mühlbrunn*," in page 165; that is, thirty-two pages beyond the page on which the sheets of paper were placed. The word was *near* the spot indicated as its site by M. A., but not this spot exactly: it was in the second line above and a little to the right of it. The words on this page immediately opposite the spot selected by M. A. were "*à-dire, de*," and it is to be recollected that there was a series of, at least, *sixty-four* words, superimposed on each other between the surface to which vision was directed, and this page. It is certainly curious that some one of these sixty-four words was not selected in preference.

This ended the trials with books. A period of repose succeeded, during which M. M. and A. seemed to be mutually comforting and consoling each other,

under what, even by their own showing, was by no means triumphant success. Meanwhile, I prepared what I regarded as the only real experiment, the *experimentum crucis*, viz.

III. The reading or divining of words inclosed in opaque covers, respecting which there could be no collusion and no delusion. I laid on the table five packets, informing M. M. and A. that each contained a French word. Four of these words were in largish print, and one written in good-sized letters. Three of the envelopes consisted of several folds—from two to six—of fine writing paper, one being gummed and sealed, the others merely carefully folded so that they could not be unfolded without this being observed. No one but myself was aware of the contents of these packets, and each was marked exteriorly with a cypher corresponding with a card in my pocket-book, indicating the word contained in each. Alexis selected one of the unsealed and thinnest envelopes, and set himself, with great apparent earnestness, and without any seeming discontent or distrust, to divine its contents. It contained the word "*Vin*," written in a large bold hand, on a piece of card. As inclosed in the envelope, the card was covered by only two thicknesses of paper (a fine wove post). Profound silence was preserved in the room, and no one was close to Alexis's chair but M. Marcillet and myself. His proceedings were—to look intently at the paper for a considerable time in different aspects, pressing it and turning it about in his hands, pressing it occasionally to his breast, forehead, and lips; but still seeming to depend mainly on *his eyes* for the accomplishment of the difficult feat. After a considerable time he said the word contained in the envelope was *printed*. No assent or dissent being expressed, after another examination he said it was *written*, and that he was wrong in saying it was printed. After another long pause, he said the word consisted of *three letters*. Still silence and expectation; and after a short time he declared *he could see nothing*, and threw down the paper. Here the "*sitting*" ended, as far as Alexis was concerned, although he remained a long time in his so-called somnambulist state, M. Marcillet soothing and comforting him, and a medical gentleman

* I mention this particularly because, at a subsequent part of the evening, M. M. chose to be extremely wroth on account of this action of shutting the book before the word was found.

—a believer in Alexis—doing the same, and also attempting to excite the phrenological organs that might lead to a more cheerful, confident, and hopeful spirit; but in vain: Alexis refused to attempt any thing more that evening.

Although the same uniform calm, cautious, and courteous behaviour towards MM. Marcillet and Alexis, was still preserved by the company, M. Marcillet several times started up in great excitement, denouncing our proceedings, proclaiming the powers of his protégé, &c. The general impression produced by his conduct was, that he was desirous of provoking some retaliation, so that he might have to allege some stronger ground than he possessed for the failure of Alexis. If this was his object, it was entirely balked by the calm behaviour of all present.

The conclusions drawn from the results of the previous exhibition (see last week's GAZETTE, p. 533) seem equally deducible from those now detailed. Alexis utterly failed, now as then, to shew, unequivocally, that power which has been called *clair-voyance*. In several cases, both on the present and former occasions, his guesses (if such they were), even when not correct, came curiously near the truth,—as, for instance, when he named the exact number of letters in the word in the envelope. The failures and blunders, however, were so egregious, and so unaccountable, on the hypothesis of the existence of a *through-seeing* faculty, that they must stagger the most credulous when fairly examined. Still, as was observed on the former occasion, the results being only *negative*, prove nothing more than that nothing was proved. It only remains for the mesmerists to adduce one or two *positive* unequivocal proofs, to put aside all our negative ones. Such proof, however, is, I believe, yet to be exhibited; and until it is exhibited unequivocally—that is, under similar guards and precautions as the failures now recorded took place—I, for one, must still remain a doubter at the very least.

Many important remarks on the strange conduct of the mesmerisers, as professors of what ought to be a matter of science, are suggested by the preceding narratives, and by the proceedings generally. I will here only

briefly refer to one point—their *inconsistency* with one another, and with themselves at different times. At the first exhibition, it was declared essential to the reading of the word in the box, that the person giving the box should *know* the word. At the second this was said by M. Marcillet to be unnecessary. And, indeed, the very practice of Alexis himself, at the first exhibition, proved that he considered this knowledge on the part of the propounder to be unnecessary; the *reading of words in the book* through a number of pages being, in fact, the very same thing as reading them through an envelope. The alleged necessity, however, of having the word known by the propounder, obviously supplied one additional means of knowing it through channels common to all; while the manœuvre of reading the book furnished the most facile and ready help to successful imposition. Again, it is maintained by some professors that the somnambulist while wide awake, as far as hearing is concerned, to the mesmeriser, is totally deaf and blind to impressions coming from others—*unless de-mesmerised in any particular sense* for the nonce. There was nothing of this sort in Alexis; he did not hesitate to confer with and understand every body who chose to address him *in relation or out of relation*, believer or infidel.

P.S. It has been thought necessary, on this and the former occasion, to be very minute and circumstantial in detailing the experiments, as it is only in this manner that a just judgment can be formed by any reader of the positive value of such experiments. Almost all the published records of mesmeric wonders, and all those I ever heard narrated, are utterly valueless, from being defective in exact and minute details. If the proceedings of Alexis, and a few more of the so-called *CLAIR-SEERS*, were followed up for a certain time, in the close manner adopted on these two occasions, we should speedily come to positive conclusions respecting the truth or falsehood of these most wonderful wonders.

July 22, 1844.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Elements of Natural Philosophy; being an Experimental Introduction to the Study of the Physical Sciences.
By GOLDING BIRD, M.D., &c., &c. The 2d Edition, revised and enlarged, pp. xlv, and 479. Churchill, London.

THIS excellent elementary work, originally designed as a text-book for the students attending the annual course of Lectures on Natural and Experimental Philosophy delivered at Guy's Hospital, has already reached a *bonâ fide* second edition; and thereby justified the praise with which we hailed it on its first tappearance. The study of the simple and unchanging laws by which the vast material universe is governed, has always appeared to us the very best discipline which the understanding can receive under any circumstances; in connection with an insight into chemistry, we regard it above all as the most suitable preparation for entering upon the study of the less exact sciences of life and organization. The additions to the present edition of Dr. Bird's *Elements*, consist of three new chapters, embracing the subjects of thermotics, and the chemical action of light. The chapter on electrominical decomposition, and part of those on polarized light, have also been rewritten. The whole work has been carefully revised, and about eighty new woodcuts are added for the purpose of better illustration.

We again recommend this neat and well-digested volume to the medical student in particular; and the connection which exists between the physical sciences, and the ordinary business and gratifications of life, point to it as an admirable source, from which the youth of both sexes, who are receiving the rudiments of a liberal and useful education, might be made to suck the first principles of much knowledge that would afterwards turn to infinite profit in their intercourse with the world. "Geography, and the use of the globes," are very well, but they are not all; they are not even the sum of what it is most important to be aware of in the business of life. We conceive

that next, to morals, physics form the proper subject of education. We should like to know this book of Dr. Bird associated in every boy's school throughout the kingdom with Hutton's Arithmetic, and the English Reader, and in every girl's school with the Abbé Gaultier, and R. Mangnall.

MEDICAL GAZETTE.

Friday, July 26, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso." CICERO.

MEDICAL PROFESSION BILL.

ON Friday evening last Mr. Howard put a query to the Hon. the Home Secretary touching this bill, which the Hon. Baronet said he would shortly lay on the table, though he did not wish it to go further, this session, than a second reading.

THE APPROACHING ELECTION OF COUNCILLORS AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

ON Wednesday next the *FIRST* election of Councillors under the New Charter will take place. This is so important an event in itself, as a recognition of the elective principle beyond the walls of the College, that although it has peculiar or personal reference to a small section of our readers only, we believe the majority of them will still watch the proceedings with interest.

The sections of the Charter which bear upon the election of Councillors are the 12th, 13th, and 14th, in which it is provided that, "upon the first Thursday in July next (1844), and at the same period in every succeeding year, or within one month thereafter, three Fellows are to be chosen, to be additional members of the Council.

"In each year in which there shall

be no vacancy, or less than three, among the life members, three of the elective members, or such less number as with the vacancies among life members shall make the number three, shall go out of office, and when there are more than three vacancies among life members, none of the elective members shall go out of office, and three Fellows only shall then be chosen to fill up three of the life vacancies, and the remaining vacancies to be treated as life vacancies for the following year or years, as the case may require."

"When the number of elective members shall be completed to twenty-four, three of the council shall go out of office annually."

"In all cases Fellows going out of office shall be eligible for re-election."

"The elective members of the Council, who shall from time to time go out of office in the manner hereinbefore mentioned and directed, shall be those who shall have been longest on the council, without re-election; and in the case of Fellows elected upon the council in the same year, those shall first go out of office whose names stand lowest (among those elected in the same year) on the book or register of the Fellows of the College."

"Whenever any vacancy or vacancies shall take place among the Elective Members in any other way than by their going out of office by rotation as aforesaid, such vacancy or vacancies shall be filled up by the election (upon some early and convenient day to be fixed by the Council for that purpose) of a substitute Member or Members in the room of the person or persons whose place or places shall have so become vacant; and every person, so elected to fill up any such vacancy, shall hold such office until the time when the person in whose room he shall be chosen would have been liable to go out of office, and he shall then go out of office accordingly,

but shall notwithstanding be eligible for nomination and immediate re-election, and, continuing eligible in other respects, his name shall be announced to the Meeting accordingly in the order and manner hereinafter directed.

The mode of election is provided for by the 15th clause, in which it is stated, "That the members of the council of the college shall hereafter be elected by the Fellows of the said college, including the members of the council as such; and such Fellows, whether members of the council or not, shall be allowed to vote in person only, and not by proxy; and that any number of Fellows (not being less than fifteen present) at a meeting convened for the purpose of electing a member or members of council, shall be competent to proceed to such election."

The provisions above extracted from the New Charter are referred to by the 5th section of the bye-laws of the College, which bears upon the election of members of Council, and where we find it provided that "Notice of the place and time appointed for every meeting of the Fellows, for the election of members or a member of the Council, shall be given to the Fellows by advertisement in the London Gazette, and in two London daily newspapers, at least fourteen, and not more than twenty-one days, before the day of election;" and "That at every such meeting, the Chairman having declared the business of the day, the Secretary of the College, or person acting for him, shall proceed to announce to the meeting the names of the Fellows, as directed by the Charter; and that in order to entitle any Fellow to be balloted for as a Member of the Council, he shall, upon his name being so announced to the meeting, be nominated in writing by three Fellows, such nomination to be delivered in to the Chairman by such nominating Fellows, or one of them,

and to contain a certificate in writing, signed by such three Fellows, testifying on their personal knowledge that the person so nominated does not practise, and has not at any time, during the five preceding years, practised midwifery or pharmacy, and that he then resides, and *bond fide* practises his profession of a surgeon, within five miles of the General Post Office in St. Martin's-le-Grand, and that he is a fit and proper person to be a Member of the Council of the Royal College of Surgeons of England."

The old system of election into the Council of the Royal College of Surgeons had certainly become very unpopular: it was unusual and un-English, and required amendment;—to have persisted in it would apparently have brought the very existence of the Royal College of Surgeons into jeopardy. Whether the system now to be tried will satisfy the great body of the members of the College or not, has yet to be seen; we sincerely trust that it may, and that we shall all henceforward be left at liberty to give our undivided energies to the advancement of the art and science of medicine, and not go on expending ourselves, as so many of us have done, in labouring the barren waste which is comprised within what is merely political in our profession. It yields nothing but crops of heartburning and excitement, which seem to us most foreign from the heart's-ease and peace of mind which we have a right to expect from our efforts as practitioners of the healing art.

But this we will say of the old system of the College of Surgeons, now it is defunct, that probably no radically vicious system of election was ever followed with so little of injustice done. In looking back upon the College of Surgeons for more than twenty years during which we have known it, we cannot see, with almost a solitary ex-

ception, that any man has been excluded from its Council who would have shed unequivocal lustre upon his seat there. Even with the exception or two which we have in our eye, we believe it very possible that, did we know all, we should say the exclusions were well grounded. If injustice have in any case been done, however, there is now, by the provisions of the New Charter, an opportunity of repairing it; and we own that we feel the greatest confidence in the good sense and the good feeling of the large body of Fellows—men of the most liberal education in the profession, and many of them in its foremost ranks—who are now about to exercise their privilege for the first time. We cannot doubt but they will do all that is right and proper to heal differences, and to secure unanimity of action, always with the grand end in view of extending the dominion and usefulness, and exalting the character, of that branch of the profession to which they have dedicated themselves.

The Fellowship, according to prospective arrangements, so far as we understand them, appears only to be open to those whose means and opportunities enable them to qualify themselves in a certain prescribed manner: we should like to see access to the honour given upon other grounds.

It is not every man whose circumstances permit him to do all that is required in the shape of preliminary education, and the number of years to be spent in the state of pupillage to the profession; yet are there men born with a natural genius for surgery; who, pale-faced on the weaver's stool (Dr. John Thomson), and besmudged in the farrier's shop (M. Velpeau), feel the call, and, amidst difficulties of all kinds, against every odds, compel their way to distinction, and make mankind their debtors in the God-like art of healing! Such men,

in the middle of the 19th century, ought not to be excluded from the Fellowship of the Royal College of Surgeons of England. As at the College of Physicians, he who labours long and earnestly, who does that for himself, by observation and the use of books, which others effect through teachers and oral instruction, ought to be eligible into the highest rank. We but throw out this hint for the consideration of the Council and Fellows of the Royal College of Surgeons, and because we do not observe, among the bye-laws of the College, any provision for the reception of Fellows under such circumstances as have been indicated above. If it be an object with such men as we have alluded to, to achieve the highest place, it ought to be no less an object with the medical corporations to have them among their leaders.

MR. GUTHRIE AND HIS COLLEAGUES

IN THE COUNCIL OF THE ROYAL COLLEGE OF SURGEONS.

ON Monday, the 22d inst. if we recollect rightly, a Petition was presented to the House of Commons, from G. J. Guthrie, praying to be heard by Counsel at the bar of the House, against the Charter lately granted to the Royal College of Surgeons of England.

Surely the course thus taken by Mr. Guthrie is rather marked by zeal than either by wont and usage or good taste. We had always held a member of a council or board to be bound by the decision of the majority. If he dissents from this decision, and refuses to be a party to its consequences, the usual course pursued is retirement. He then proclaims the cause of his secession, and so gives all parties interested the cue as to what is going on, and is farther at liberty to give his best assistance in settling matters to rights, according to his view of what constitutes right. We hold Mr. Guthrie's

hands tied both in courtesy and honour, so long as he retains his position at the Council table of the College of Surgeons. His oath on taking his seat binds him to reserve; universal custom bids him bow to the decision of the majority of the body of which he is a member.

MARYLEBONE AND PADDINGTON HOSPITAL.

THERE is now the certainty that this projected institution will speedily be founded on a scale commensurate with the amount of deficiency in hospital accommodation conspicuous in the north-western quarter of the metropolis. At the beginning of the present century the parish of Marylebone did not reckon more than 20,000 inhabitants; that of Paddington no more than about 2,000. At the present time Marylebone counts 150,000, Paddington upwards of 30,000 souls, and both are still rapidly increasing. Twenty years ago the Edgware road fairly bounded London to the North and West; we have but just seen a city of palaces rise up beyond it. Yet all this extension of building, this increase of population, had gone on without any adequate measures having been taken to meet the exigencies of the poor when prostrated by disease, and when overtaken by accident, of the description of that which the humanity of mankind in all civilized societies of modern times has prompted them to provide: The north-western division of London has hitherto been without any hospital for the reception of the sick and maimed among its poorer inhabitants. The consequence has been, that it has still had to go begging to a distance for the hospital accommodation it required when serious accident overtook any of its labourers or mechanics. This slur upon the charity and humanity of the new district of the metropolis, it seems will now be

speedily remedied. At a public meeting, held last week in the theatre of the Western Literary and Scientific Institution, Edwards Street, Portman Square, Earl Manners in the chair, it was announced that no more than about £1200 were wanting to make up the sum of £15,000, which the managing committee of the proposed Marylebone and Paddington Hospital had pledged themselves to collect before they proceeded to make any arrangements for building. A site for the hospital has been presented by the Grand Junction Waterworks Company, at the instance of the Bishop of London, Mr. Thistlethwayte, and the trustees of the Paddington estate,—in short, the prospect, which for a long time was gloomy enough, has gradually cleared up; commenced amidst difficulties, and discouragement, and opposition, difficulty, discouragement, and opposition, have all faded away before the perseverance of the provisional committee; many who were lukewarm friends at first are now zealous advocates; and it seems certain that, when the walls of the building are seen emerging from the ground, there will be half as much money again as was originally looked upon as a sum impossible to be collected.

Even since the last great public hospital was built, great progress has been made in the knowledge and practical application of the best principles of ventilating and warming buildings: these, of course, will be made available in reference to the new hospital and we cannot doubt with effects on the results of great operations, and the treatment of disease in general, the beneficial magnitude of which are yet unimagined. By spending a large sum of money in improving its sewers, the Governors of the London Hospital reduced the mortality of that great establishment by two per cent. annually—instead of nine deaths, there have been but seven per cent. since the improve-

ments took place. Important as draining certainly is, it is still very much less important than efficient ventilation and due temperature. We do not despair of seeing the mortality in the new hospital as low as five or six per cent.

The acting committee of the new hospital are reported as of one mind in regard to the ends and objects of such an institution: it should be found, not only a means of benefit to the individual by relieving him under the pressure of sickness, but a means of advantage to society as a school for medical practitioners. It may be maintained, indeed, that hospitals are much less useful to individuals than to the public, to the world at large. Our great hospitals are not merely the schools from which we within this sea-girt island, this little spot of earth, are supplied with the men in whose hands are the lives and well-being of all we hold dearest; they are also the schools whence the West Indies, the vast peninsula of Hindostan, the Cape, and the fifth division of the globe—New Holland, are furnished with those best heralds of civilization and improvement, intelligent medical practitioners.

This consideration we trust will influence the committee in drawing up the rules and regulations for the government of the new hospital. Whilst every precaution is taken that will insure its being made at once an efficient school for the education of medical men, and a means for the relief of human suffering, we trust that its offices will neither be made heirlooms, nor matters of course, nor life tenures, as they are so generally. The public have a title to a somewhat numerous succession of men with the experience which the connection with a large hospital so generally bestows; and as in the Edinburgh Infirmary, the Glasgow Infirmary, and some we believe among the provincial hospitals of England, the

offices of physician and surgeon ought to be tenable for a certain number of years only. This would probably be the best mode of securing to the greatest number the greatest possible amount of good derivable from such an institution; a consideration of no trifling importance. We shall probably find opportunity of reverting to this interesting subject again.

MESMERISM EXPOSED.

LONDON has lost the *advantage* for the present of the exhibitions of Monsieur Alexis, and his master, M. Marcillet, the author, we presume, and the *entrepreneur*, of the venture across the channel—they are both gone; set off for Paris yesterday! Dr. Forbes has the honour, upon this occasion, of having stripped off the flimsy veil of imposition under cover of which these mountebanks attempted to deceive the public. There never was exhibition so pitiful, never exposure so luminous, never defeat so complete, as that to which the notes of a second exhibition, published in this day's *GAZETTE*, refer. Press of matter compels us merely to refer to these capital notes meantime, which our readers will find in a preceding page. If we catch ourselves in the humour next week, we shall give mesmerism "another and a last word" before finally sealing our lips, and putting a veto on our pen in regard to the silly and wicked subject for ever. At present, however, we request our readers' best attention to the following *morceau de politesse* addressed by M. Marcillet to our worthy contemporary, the editor of the British and Foreign Medical Review. We do not know what our friend has said by way of giving M. Marcillet a peg to hang his abuse upon; we presume it must have been something subsequent to the "Second Exhibition," for there the editor of the *British and Foreign* showed the greatest

command of his temper, and only did not turn M. Marcillet out of his house for impertinence and playing the bully, in deference to the *presumed scientific character*, God save the mark! of the exhibition. We should only mar the letter by translating it; we beg those of our readers who do not understand French to send for a grammar and dictionary forthwith, in order that they may qualify themselves to appreciate at its full value "*mesmeric politeness*" and the "*mesmeric style*."

MONSIEUR FORBES,

Je regrette bien sincèrement que dans votre aveuglement sur le Magnétisme, vous vous soyez porté à des excès en traitant de charlatan un homme qui n'a rien fait pour mériter cette épithète: jamais, monsieur, depuis que je fais du magnétisme, je n'avais été aussi malhonnêtement abimé, et je vous avoue que vous payerez cher ce mot, d'abord par la persévérance que je mettrai lorsque je reviendrai à Londres à faire de nouveaux prosélytes; c'est ainsi, je l'espère, que je serai vengé de tant de malveillance de votre part. Vous n'avez rien considéré, en tout ce qui me touche, ni ma position de négociant à Paris, où je suis établi depuis plus de 19 ans, ni les antécédents honorables de ma vie privée; vous n'avez fait aucune recherche pas plus sur le magnétisme que sur moi-même; vous avez été bien coupable, monsieur; vous n'avez même pas compris la sympathie dans le magnétisme; et vous êtes médecin!

Samedi prochain, dans le *Medical Times*, je serai déjà vengé un peu de vos turpitudes; et les expériences que je fais journellement prouveront à toute l'Angleterre le cas qu'elle doit faire sur vos observations scientifiques; les cinquante témoins présents à la séance de la rue Mortimer certifieront en besoin, que votre conduite a été perfide et malveillante; et prenez bien note, que j'emploierai tout ma pouvoir si je reviens à Londres, comme je l'espère, pour convaincre le plus de médecins possibles, afin que vous restiez anéanti, réduit au silence, ou si vous l'aimez mieux, *prêchant dans le désert*, c'est la triste consolation que j'ai laissée à quelques Docteurs Travaux qui comme vous a condamné sans comprendre.

Pour que vous compreniez bien aussi que le mot de charlatan ne peut m'être appliqué, c'est que vous saurez que mon sujet et moi sommes plus que fatigués du travail magnétique, c'est à dire de l'enervement que l'on éprouve en magnétisant, et certes un charlatan ne s'enrève pas. Vous saurez que je préfère donc rentrer à Paris que de rester en es

moment à Londres, où je refuse plus de cinquante séances de magnétisme, assez productives. Un charlatan n'aurait rien refusé. Puisse la leçon que je vous promets vous rendre un jour moins insolent, c'est le vœu que je fais pour votre conversion.

J'ai l'honneur de vous saluer,
MARCILLET.

Londres, ce 23 Juillet, 1844.

PRESENT TO MR. LANE.

LAST week the friends and former pupils of Mr. Lane presented him, through the hands of Dr. Wilson, of St. George's Hospital, with his portrait, in testimony of their respect for his private character, and of their grateful sense of his merits as a teacher.

He who has spent a dozen years and more of the best period of his life in teaching anatomy, the foundation of all medical science, deserves consideration not only at the hands of his friends, but of the public at large; and Mr. Lane's circle have done as well in making an opportunity to express the sense they entertain of his deserts in the laborious and health-destroying duty which he has so long and so ably performed, as they have shown good taste in the means and manner of proclaiming their esteem and approbation. A portrait is a thing that is somewhat costly, but it is generally without intrinsic worth; it is therefore one of the *purest* means by which a public man's friends can tell him how much they love and honour him; it is also the thing which he can accept with highest propriety, with the least of suspicion that he or his other self in some peculiarly intimate and interested friend, had aught to do in suggesting or effecting the present.

Next to the secret consciousness of desert, is the public acknowledgment by contemporaries of our well-doing, and we therefore congratulate Mr. Lane on the very appropriate tribute that has just been paid to his character and accomplishments.

LETTERS

FROM DR. EVORY KENNEDY, DR. MARSHALL HALL, DR. JOHN DAVY, AND DR. KNOX,

ON THE

NERVES OF THE UTERUS.

[THERE have probably been more false facts than false theories in medicine. It might almost be said that in proportion to the difficulty of demonstrating a stated fact was the facility with which it was admitted, and in proportion to the facility of demonstration was the difficulty of obtaining acknowledgment. The main business of the world of physiological science up to a very late period has actually been to correct errors in matter of fact committed by predecessors in the path of observation. For our own part, we believe that no better or more complete demonstration of any fact in anatomy was ever made than that of Dr. Robert Lee in regard to the nerves of the uterus. Still our friend complains that his demonstrations are not even generally admitted; and he has procured the letters of several gentlemen whom he thinks the world acknowledge as competent judges on an anatomical question. Conceiving that it is really matter of great moment to come to a conclusion on the subject of the nerves of the uterus, we give insertion to these letters at Dr. Lee's request.—*ED. GAZ.*]

From EVORY KENNEDY, M.D., *late Master of the Dublin Lying-in Hospital.*

My dear sir,—I have a perfect recollection of the gratification I experienced at examining along with you your preparations of the nerves of the uterus. Most schoolmen admit the simplest of all sensible proofs to be *demonstration*; and where, as in your case, the fact at issue is capable of being tested by such proof, I am at a loss to know how a question can arise on the matter. For myself I can only say that I was as satisfied that what I saw was nervous and ganglionic structure, as I am of the existence of nervous structure in any other organ of the human body with which I am familiar.

Believe me,

Yours very faithfully,

EVORY KENNEDY.

Merrion Square, Dublin,
January 17th, 1844.

To DR. LEE.

From MARSHALL HALL, M.D., F.R.S.

I have on several occasions most carefully examined the anatomical preparations of the uterus by Dr. Robert Lee, and I have no hesitation in saying that in my opinion they display a system of ganglia, nervous loops,

and nerves belonging to the uterine system, of great extent and importance.

MARSHALL HALL, M.D.

14, Manchester Square,
February 1844.

To Dr. R. LEE.

From JOHN DAVY, M.D., F.R.S.

The Oaks, Ambleside,
March 25th, 1844.

My dear sir,—Now that I am at home, and have leisure, let me thank you for the gratification I had, when in town, in seeing your preparations displaying the nerves of the uterus in its unimpregnated and pregnant state. I never witnessed any anatomical demonstration more satisfactory; indeed I cannot but consider your dissection of these nerves as a *perfect demonstration*. Dr. Graves, I perceive, in his *System of Clinical Medicine*, p. 474, says, "Tiedemann has proved beyond contradiction, that the nervous matter of the womb is augmented to a very remarkable degree during the impregnated state, and that minute nervous filaments, scarcely discoverable with the aid of a microscope, enlarge into bands visible to the naked eye." He does not refer to your observations, which, I take for granted, were anterior to the German Professor's, and consequently he has not done justice to you.

I remain, my dear sir,
With much esteem, faithfully yours,
J. DAVY.

From ROBERT KNOX, M.D., F.R.S.E.,
Lecturer on Anatomy.

Edinburgh, Newington,
29th June, 1844.

Dear sir,—Since my return to Scotland, I have turned over in my mind the opinion I offered you in Saville Row, whilst examining the very beautiful preparations you shewed me of the "nerves of the unimpregnated and of the gravid uterus;" and the opinion amounted to this: that what you shewed me as *nerves, ganglions, and nervous filaments* of communication, are really such, and can be nothing else: that the increase in size or bulk to which so much importance has been attached has been upon the whole somewhat exaggerated by those who have adopted a different view from that I now propose: that the preparations you shewed me are without exception the most beautiful I have ever seen of any part of the nervous system: that viewed simply as dissections of a structure difficult to unravel, they merit the highest praise; but taken in connection with the physiology of the organs, they place the dissector in the foremost place of observers.

Believe me to be, very faithfully yours,
ROBERT KNOX.

To Dr. ROBERT LEE.

BEING A
WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

FRIDAY, AUGUST 2, 1844.

REPORTS,

BY H. FEARNSIDE, M.B.,

OF

CASES TREATED IN UNIVERSITY
COLLEGE HOSPITAL.

With Clinical Remarks by

DRS. WILLIAMS, TAYLOR, AND THOMSON.

Acute articular rheumatism, complicated with endocarditis—Relapse and return of the rheumatism, accompanied with bronchitis—Treatment antiphlogistic, combined with the exhibition of colchicum.

FREDERICK WEBBER, æt. 16, admitted into University College Hospital, under Dr. Williams, May 13th. A youth of florid complexion, and moderately stout conformation; he is a native of, and has always resided in London; his food has been wholesome and in sufficient quantity; his occupation is light but sedentary, being that of "trimming" the articles in a papier-machée manufactory. His parents are living, and although not healthy, yet neither they, nor any of his brothers or sisters, have at any time suffered from rheumatism.

His health has generally been good; he has no recollection of having suffered from any serious disease, except about three years ago, when he had an attack of subacute rheumatism, occasioned by his imprudently bathing when hot. The knees and ankles were the parts chiefly affected; he was at that time about a month under treatment in University College Hospital; he has no remembrance of having had any palpitation, or other symptom referrible to the heart; and no mention is made in the report then taken of his case, of the existence of any disease of that organ. He has recently had an attack of syphilis, for which he has taken mercury in rather considerable quantity.

Present attack.—On Monday last (May

8th), owing to the absence of one of the other servants of the establishment where he is occupied, he was obliged to walk about, carrying out parcels, &c. for the whole day, which was very rainy; he was consequently much fatigued, and his clothes were wet. On the following morning he was unable to rise, his limbs feeling stiff and sore, and he had much headache, thirst, and heat of skin. In the afternoon he experienced severe pain in the right elbow, which became much swollen. On the following day his right ankle was attacked; he perspired profusely, and felt worse in every respect. On Thursday both knees became swollen and painful, and the febrile symptoms continued. No measures having been adopted for his relief, he remained in this state until his admission (Saturday).

Present state.—The skin is very hot, although he is perspiring profusely; he complains of excessive pain in the right elbow, both knees, and the right ankle. The elbow is considerably swollen, and somewhat red; the capsules of both knee-joints are distended with fluid; there is also some swelling in the bursæ around the joints; there is some redness of the integuments, but not much swelling of the ankle. The left elbow is slightly affected. The pains are neither increased nor relieved by warmth.

The countenance is heavy and anxious; the face is flushed: he has no headache, but complains of inability to sleep on account of the severity of the pains. He has no pain about the chest, or dyspnoea; has a slight cough; respirations 22 per minute.

The impulse of the heart is too strong and extended; there is increased dulness on percussion over the cardiac region, extending from the lower border of the fourth rib to the margin of the chest inferiorly, and transversely from a particular line descending from the left mamilla on the one hand, to the left border of the sternum on the other. A slight murmur is heard with the first sound of the heart over the situation of

the apex of the organ, but it is most distinctly heard midway between the left mamma and the margin of the sternum; it is heard also at the top of the sternum, and over the arteries of the neck; it is audible with remarkable distinctness over the left subclavian artery. Pulse 106, and slightly jerking. A sort of pulsatory or vibratory movement is perceptible with each beat of the heart, between the third and fourth, and still more distinctly between the fourth and fifth ribs on the left side.

The tongue is covered on its centre with a yellowish brown fur; the gums are turgid, and have a blue tinge around the teeth; the breath has a mercurial foetor. He has some soreness of throat, and the uvula, tonsils, and pharynx, are more than usually red; he is very thirsty; has no appetite; bowels rather confined; no enlargement of the liver; urine strongly acid, sp. gr. 1132, and contains a large excess of urea, being almost converted into a solid mass on the addition of an equal volume of nitric acid.

Treatment.—Venesection was directed to be performed to the extent of 14 oz.; calomel and opium to be given at bed-time for two nights, and an aperient (senna) in the morning; and an alkaline draught containing colchicum wine (3ss.) to be taken three times daily. The patient was also placed upon low diet.

May 14th.—He expresses himself as feeling better upon the whole. The pain in the right knee has abated considerably, but it has increased in the left one; and both elbows are now swollen and painful. Pulse 88, and soft. The blood abstracted is cupped, and presents a thick buffy coat.

15th.—The capsule of the left knee-joint is much distended with fluid, and he experiences severe pain in the part; the swelling of the right knee has subsided. Both elbows and wrists are considerably swollen and painful, especially those upon the right side; but the inflammation does not appear to extend beyond the immediate vicinity of the joints; he perspires less, and the face is less flushed. He complains of tenderness upon pressure over the cardiac region; the morbid sound and dullness on percussion remain as before; pulse 96, soft and small; respirations 24 per minute. The tongue is dry and furred; no sickness; bowels open; urine acid, sp. gr. 1029, and contains an excess both of urea and lithic acid.

16th.—The swelling of the left knee is still more considerable; the elbows continue swollen and painful; the small articulations of both hands are now affected. The skin is warm and moist; pulse 84, stronger, and rather jerking. (The bleeding to be repeated.)

17th.—He is able to move his knees, but there is still much swelling about the left

one; the elbows and hands are less swollen, but he complains of pain in the shoulders. Skin cooler; no sickness; bowels open. The cardiac dullness on percussion appears less extensive; pulse 84, and softer; respirations 24 per minute. The blood abstracted yesterday is much buffed and cupped.

18th.—The rheumatic symptoms have subsided in a great degree, there being merely slight swelling of the left knee-joint and left metacarpo-phalangeal articulations, and some pain in the left shoulder. The surface is warm and moist; the cardiac dullness on percussion appears to be considerably less extensive than a few days ago; in addition to the morbid sound with the systole of the heart, there is a clangorous murmur with the second sound, and heard over the base of the organ. Pulse 72, soft and small.

During the following week the patient's improvement was very marked; he remained free from the rheumatism; the tongue lost its fur, the appetite improved, and he slept better; the urine no longer contained any excess of urea or lithic acid; its specific gravity was usually about 1020, and instead of being strongly acid, it was frequently alkaline in reaction, as he continued to take the alkaline draught, the colchicum being omitted, and its place supplied by the iodide of potassium. Having ventured out of doors on May 25th, he appears to have then taken cold, as on the following day he began to suffer from soreness of throat, and cough, and had a slight return of the rheumatism in the left arm. The colchicum was directed to be resumed, and a dose of calomel and opium, followed by a brisk purgative, was prescribed.

29th.—The relapse has become decided; he has much pain in both knee-joints, the capsules of which are considerably distended with fluid; the right elbow is also somewhat swollen. He has a frequent short cough, and complains of pain in the left side of the chest; he has some dysphagia, and the tonsils are enlarged; there is no increase in the cardiac affection; pulse 96, moderately firm; respirations 26 per minute. Over the lower and posterior part of the left side of the chest a submucous rhonchus is heard.

30th.—The right shoulder has become swollen and painful, and the wrist and small joints of the right hand are slightly affected. He has some headache and thirst; skin warm; the cough continues troublesome, but is unattended by expectoration; pulse 96. (Four grains of iodide of potassium to be added to the draught.)

June 1st.—The rheumatism has left the right arm, and established itself in the large joints of the left one; the knees continue swollen and painful; he perspires profusely,

is thirsty, and sleeps but little; pulse 100, moderately firm. A liquid rhonchus is still heard over the lower part of the left side of the chest; the morbid cardiac sound, and dullness on percussion, remain as before.—(Venesection to be repeated to 10 oz.)

2d.—The swelling of the knees appears to have increased rather than otherwise; the articulations of the fingers of the left hand are swollen, red, and painful; he has also much pain in the left shoulder; the urine is scanty, high-coloured, sp. gr. 1026, and acid. The cough has been more troublesome, and he has expectorated some greenish-yellow mucopurulent matter. A mucocrepitant rhonchus is heard over the lower part of the right side of the chest.

3d.—A striking improvement has occurred since yesterday; the pain and swelling of the joints are rapidly subsiding; pulse 88, and soft; urine acid, sp. gr. 1024, and contains a large excess of saline matter.

From this time the patient continued to improve uninterruptedly. On the day following the date of the last report the rheumatic symptoms had disappeared, the cough became less troublesome, and he regained his appetite and strength. The bronchitic rhonchi ceased, but the murmur accompanying the first sound of the heart remained audible as long as the patient was under observation, although less distinctly so than upon his admission. He was discharged cured on June 19th.

REMARKS.—The nature of the disease in this case was clear: migratory inflammation of the joints, and of the *large* joints in particular, attended with fever, not paroxysmal, is the character of acute rheumatism alone. The disease in this instance was of the articular variety, there being inflammation of and effusion into the synovial capsules, and also the bursæ around the joints; whilst the intermediate fasciæ were but slightly if at all affected.

The attack was a severe one; the patient was predisposed to the occurrence of the disease, by having formerly been the subject of it. He had also been for some time under the influence of mercury, and was thus rendered more susceptible of injurious impressions from various agencies.

Few causes are more powerful in producing rheumatism than considerable exertion, and exposure to cold and damp combined. The former, by causing large destruction of the muscular tissues, would appear to act by affording the pabulum, which either directly, or modified in some manner by the vital chemistry, constitutes the "materies morbi" of rheumatism. The latter causes may act in several modes, but chiefly, in all probability, by occasioning a diminution or temporary suppression of the cutaneous transudation; as a result of which,

an increased quantity of fluid, and also of the lactates usually eliminated by the skin, must be thrown upon other parts. The subsequent inflammation of the fibrous tissue is, no doubt, connected with this altered character of the circulating fluid.

The rheumatism in the present instance was complicated with an affection of the heart; this may have been either recent or of some duration; the increased dullness on percussion, the extended and forcible impulse, and the morbid sound, may be attributed either to recent endocarditis, or to dilated hypertrophy of the left ventricle, with some accompanying valvular disease. No mention is made of any affection of the heart in the former reports of the case, and were we to rely upon the patient's own sensations, we should conclude that the organ escaped in the former attack; but this would be an unsafe criterion, as it is well known that the heart may be seriously implicated without the patient being at all conscious of it. But, from the former attack being only subacute, from the severity of the recent one, and especially from the fact that the dullness on percussion diminished in extent, the impulse became less strong, and the murmur less distinct, before the patient left the hospital, it appears probable that the disease was recent.

The situations over which the morbid sound was most distinctly heard, viz. over the base of the heart, and along the course of the blood-vessels, pointed out the aortic valves as its seat; and its accompanying the systole of the heart indicated the existence of some obstruction to the exit of the blood. A few days after the patient's admission another murmur was heard in the same situation as the former, but during the diastole of the heart, implying regurgitation into the ventricle; the duration of the sound, however, was very short.

The pain in the joints in this case was unaffected by variation of temperature; the absence of any relation between its increase or diminution, and exposure to heat or cold, has been observed in other instances, proving that this symptom cannot be relied upon as an indication of the acuteness of the attack.

The changes which the blood and urine undergo in acute rheumatism were strikingly seen in this case: the small, firm, highly buffed and cupped crassamentum, was such as is not often seen in any disease but acute rheumatism; the urine was of high specific gravity, and loaded with urea and lithic acid.

The fever was very considerable upon the patient's admission: the pulse was 106, and the skin hot, although bathed in perspiration, and consequently subjected to the cooling process of an unusual degree of evaporation. It seems calculated to excite surprise, that the persistence of the symptoms in acute

rheumatism, notwithstanding the profuse discharge of fluid by the skin in many cases, should not have led to the natural inference of the questionable utility of sudorifics in this form of the disease.

The efficacy of the treatment was equally obvious in this as in the last case commented upon; four days after it was commenced, the patient could move his limbs without pain, and on the following day the joints were almost free both from pain and swelling, and the frequency of the pulse was reduced to 72; on the eighth and ninth day, he might have been pronounced convalescent. And a few days afterwards, from premature exposure of himself, he had a return of the rheumatism in a very severe form, and this relapse persisted for about a week, and was accompanied with signs of bronchitis in the lower part of both lungs. From the greater amount of fever present in this case, as well as from the inflammatory affection of the heart in the first instance, and that of the bronchial tubes subsequently, the treatment upon the whole was more decidedly anti-phlogistic than that pursued in the case whose history was last recorded. Notwithstanding the severe recurrence of the disease and its complications, the patient was free from rheumatic or other notable symptoms in twenty-two days, and was discharged in twenty-seven days from the period of his admission, or in thirty-one days from the period of the attack, which is considerably within the limits assigned by most writers for the average duration of the complaint.

A SHORT ACCOUNT
OF A
ONE-EYED HUMAN MONSTER.

By D. J. T. FRANCIS, M.B.
(For the *London Medical Gazette*.)

THROUGH the kindness of Mr. Heath, Honorary Surgeon to the Union Hospital of this town, I had the opportunity, some 18 months since, of examining an unusual form of monstrosity. In submitting these short notes for publication, I cannot refrain from expressing regret that the subject was irretrievably destroyed, by a person ignorant of its nature, long before the dissection had been completed. The observations, however, were made at the moment, and, short and disjointed as they are, it has been suggested to me that they are not altogether without interest. At any rate it is hoped they may do something more than merely

excite regret for the small profit made of the occasion.

The monster in question, which was a female, had a well-formed body and limbs, of the usual size at about the eighth month of utero-gestation. The head was nearly half as large again as natural, reposing upon the spine in almost a straight line, having but a trifling angle forwards; and, except at its posterior part, deviated in most respects from the normal form. In the usual situation of the frontal bone, arose a large, prominent, uniformly-rounded tumor, evidently the result of a deficiency in that part of the bony parietes, and rising forwards was palpably filled with fluid. This tumor was partly covered with hair.

Immediately below it was a single eye, perfectly central, sunk in no depression, but on an uniform level with the surrounding parts. Besides this eye no feature of the face was present; not a trace of mouth, nose, chin, or cheeks; but, about an inch beneath it, were situated the external ears, which, owing to the abrogation of the parts just mentioned, were enabled to approximate within an inch and a half of each other. Their long axes moreover had assumed nearly a transverse direction, their lower extremities being turned forwards; in which direction the meatuses also pointed; so that the only space which could have represented the face, even if any features had existed, was scarcely an inch and a half square.

The integuments of the head being reflected, the occipito-frontalis muscle and tendon were brought into view, forming, with the dura mater, the bulging walls of the tumor. On continuing the incision into the cavity of the skull, about two or three pints of clear amber-coloured fluid were evacuated, and, in the centre of the floor of the posterior and middle fossæ, was disclosed a flattened, tongue-shaped process of nervous matter, protruding forwards from the spinal canal, and representing all that existed of the brain. It was three inches long by one and a half broad, symmetrical, azygous, without salient points, or trace of hemispheres or convolutions; its more important features, however, as of other parts of the nervous system, were reserved for a future examination, which was, unhappily, frustrated.

The occipital, parietal, and squamous

portions of the temporal bones, had their usual forms and relations to each other, and appeared, from the progress of ossification, to have been eight or nine months old. The only trace of the frontal bone consisted of a narrow, ring-like portion, about two lines in breadth, just sufficient to form the coronal suture: the true frontal and orbital portions were altogether absent.

This deficiency in the frontal bone, and also of the sphenoid (for little else than the body of this latter bone was present), and protrusion of the cerebral capsule, constituted a kind of *spina bifida* of the first of the three cranial vertebræ.

The middle and posterior fossæ of the base of the skull were of the usual capacity, whilst the anterior was, of necessity, altogether absent. The styloid process of the temporal bone, not ankylosed with the petrous portion, gave attachment to its proper muscles.

Of the bones of the face no vestige appeared, the finger, when directed to this part from before, impinging at once upon the body of the sphenoid bone, the skin alone intervening.

The eye was imbedded, as usual, in a quantity of soft fat, but was unsupported by any trace of bony orbit. There was present, however, what might be considered a peri-orbit, a continuance of the dura mater or cerebral capsule, which invested the optic nerve, and proceeding anteriorly, supported the eye, and blended at its extremity with the skin and tarsal cartilages.

The recti muscles of the eye were all present and well developed; their origins encircled the optic nerve, and appeared to arise from the periorbital membrane before alluded to, whilst their anterior attachments were normal. The superior oblique followed the usual course, its tendon passing through a membranous trochlea situated on the right side of the globe.

Of the auditory apparatus the only parts of which any rudiments appeared were the external ear, the meatus, and Eustachian tube. The former was large, but was remarkable only for the transverse direction it had assumed. The Eustachian was a continuous tube from the external meatus to the pharynx, of the same diameter throughout, and uninterrupted by any vestige

of tympanum; it pursued a direction inwards, backwards, and slightly downwards, was a little curved, and lined with a smooth, whitish, mucous membrane. Its internal termination was at the posterior and upper part of the pharynx, immediately below the spine; the aperture was round and patulous, and very far exceeded in size the corresponding part in the adult. The whole length of this breathing tube, which, it should be observed, owing to a deficiency of the petrous portion, was in contact with bone by its upper surface only, was ten lines, and the distance between the internal extremity of either tube seven lines.

There was nothing unusual about the larynx; its diameter was three lines. The epiglottis was well formed.

The pharynx was capacious and had the ordinary relations; the only openings, however, into it were of the Eustachian tubes, the larynx, and the œsophagus. About a line above the os hyoides, which presented no peculiarity, was a bundle of muscular fibres having a transverse direction, the extremities, however, being somewhat deflected, so as to bear some analogy to an orbicularis oris; it formed the upper boundary to a transverse slit, which terminated, at no great depth, in a cul de sac, and suggested a resemblance to the mouth. On removing this muscular layer, a small, but well-formed tongue, shrunk down upon the os hyoides, was disclosed.

The bronchi and other contents of the thorax were quite natural; the lungs, collapsed at the sides of the spine, had received no air. The abdomen and limbs were perfect.

The various deficiencies in the head of this monster furnish some interesting examples of unequal advance and arrest of development during the transition from the simple to the more perfect condition. But there is something else than mere permanence of an early condition; for the eye was central, and the optic nerve traversed the sella turcica in the mesial line, a position it is never known to assume in the normal state during any period of uterine life. Two suggestions occur in explanation of this central single eye; either that it was the result of an early coalescence of the two, or that one was entirely absent, or so rudimentary as to have escaped detection.

Of these, the former view is probably the more correct, for it accords with the symmetry which was observed of corresponding parts on either side of the head: moreover, in the centre of the margin of the upper tarsus, a slight indentation or notch was clearly perceptible, as if betokening a line of separation, and the two canthi bore the form of the external one in the natural eye. The only circumstance in support of the latter view was the existence of a single superior oblique muscle, which was attached to the right side. No satisfactory inference can be drawn from the presence of four only of the recti muscles; they may have been either proper to a single eye, or the external muscles of two united eyes. The subject was, unfortunately, destroyed before any dissection had been made of the internal eye.

The absence of any trace of nostril, and perhaps of true ear*, was connected, probably, with the absence of the nerves of the corresponding senses, and pointed to the fact that these diverticula from the brain exist prior to the formation of the organs in which they are destined to be lodged.

There was, in the perfect formation of the middle and posterior fossæ of the skull, and other circumstances, reason to believe, that the brain had been, at one time, more fully developed than it was found to be at the examination; and that it had, together with some of the bones, suffered subsequently from the accumulated pressure of the fluid within the skull.

The main interest, however, of the case lies in the singular modification of breathing apparatus, which, judging from the scanty literature I am enabled to consult, is unrecorded. There is no doubt that, so far as a mere passage for air to the lungs is concerned, the Eustachian tubes would have amply fulfilled this office; for their conjoined calibres were even greater than that of the trachea, and, as in the apparatus there was nothing superadded, but a simple arrest in the development of parts, considerable testimony is added to the opinion of Huschke, who views the Eustachian tube as the remains of the superior of the bronchial apertures; the necessity for the permanent existence of this latter, in the present

instance, resulting from the occlusion, or rather absence, of mouth and nostrils.

It is perhaps hardly profitable to glance at the curious medico-legal question which might arise if the abstract viability of such a monster were discussed. With a good chest and lungs, and with air-passages of sufficient dimensions leading to them, it is clear that the physical conditions for the performance of respiration were all present. The tubes, moreover, communicated with the pharynx and stomach, and although breathing had not in reality commenced, no light can be thrown in explanation of the fact of viability, in the absence of any knowledge of the circumstances attending the birth.

Manchester, July 17th, 1844.

**CASE OF
VENEREAL SARCOCELE IN EITHER
TESTICLE SUCCESSIVELY;
ATROPHY OF LEFT, RECOVERY OF RIGHT
TESTIS.**

BY T. M. SUNTER,
Assist. Surgeon 7th Rl. Fusiliers.
(Communicated by the Director-General of the
Army Medical Department.)

PRIVATE JOSEPH STUBBS, 7th Royal Fusiliers; admitted into the Depot Hospital at Brecon, South Wales, February 16th, 1844, complaining of hoarseness, cough, and a pain in his left testis.

The patient is unmarried; of a strumous-looking habit, fair hair, blue eyes, pallid and rather sallow complexion. He was first a butcher, and then a gentleman's servant, before he entered the army; states that he was always very healthy before he enlisted. His first illness was at Portsmouth, in 1832, where he had cholera. Next in Malta, where he had a sore on the penis, which was treated and healed by local applications, and was not, he states, followed by secondary symptoms. His next illness was in Dublin, 1838, when he was, he states, four months in the General Hospital there, for a discharge from the ears, with deafness, and was sent out cured. He was admitted a second time in the same year, into the same hospital, for jaundice, and was discharged cured, after having been, as he says, five months under treatment. Character good, but drank as much as his pay allowed him to do.

* The absence of the tympanum alone was demonstrated, and not of the true ear.

On referring to a former register, I find him admitted into hospital October 6th, 1841, at Cork, where the dépôt of the Fusiliers was then stationed, for a small inflamed pustule, which was observed on the foreskin after impure connection; which soon broke, and was converted into a foul, sloughing ulcer, attended with much swelling, redness, and pain. The ulcer occupied two-thirds of the prepuce; its edges were irregular, elevated, angry; its surface was foul, and covered with bloody sloughs, and discharged a thin fetid sanious fluid, mixed with blood; the sloughing extended through the prepuce by an opening about the size of a shilling. The pain was not very severe, and the swelling rather less than might have been expected; its colour florid. Little constitutional disturbance existed. Tongue clean and moist. Pulse 90, soft.

The ulcer was touched several times with undiluted nitric acid; the man was put on spoon diet, well purged with calomel and jalap, and went through a course of pills of calomel, antimony, and opium, till the mouth became rather sore, when the ulcer healed.

The following year Stubbs came into hospital again, affected with slight gonorrhœa, and hernia humoralis of right testicle, which was much swollen, complaining also of pains in his lower extremities, especially along the shin bones. No fever. He was vomited, had leeches applied to the testis, &c., and gradually improved; but the testicle continuing large and hard, he was put on a course of blue pill, and then of iodide of potassium. By and by, the unguent. iodinii was rubbed into the testis, which was further bound about with strapping. He had also tonics for a time; subsequently he was treated for rheumatism by means of colchicum and diaphoretics. An abscess then formed in the right leg, but disappeared by absorption, and there was considerable pain and contraction of the right elbow.

In the middle of February 1843, Stubbs shewed decided indications of hectic; he had chills and flushes in the afternoon, and awoke in the morning unrefreshed, and bathed in perspiration; he also began to complain of hoarseness, cough, and at same time of a pain in left testis, which swelled, and

soon attained to the size of a turkey's egg: the right testis, which had been formerly affected, was partially atrophied, and only half the size of a healthy testis, but it was sensible to pressure.

I had at this time put down the case as "rheumatic orchitis," with "subacute laryngitis;" looking on the latter as a form of the then prevalent "influenza," and copying the former from the old register, in which the affection of the right testis was so designated.

The patient was purged, placed on low diet, and the scrotal veins, which were much enlarged, were pretty freely punctured, to the great relief of the patient. Blue pill and opium were prescribed until the mouth became sore. The patient improved, but the testicle still felt hard, and was in some parts tender on pressure; anteriorly there was a distinct feeling of fluctuation.

I now changed my opinion of the nature of the case, and wrote it down "hydrosarcocele of left testicle, I think syphilitic," and therefore determined to administer mercury, in the manner recommended by Sir Benjamin Brodie, in a lecture on the use of mercury in syphilis, delivered at St. George's Hospital last February. But as the mercury I had just been giving him had taken effect rather suddenly and severely, and as he was still suffering from mercurial irritation, I judged it better, before putting him under a second course, to give him tonics, with a more generous diet.

In ten days he commenced rubbing in half a drachm, and then a drachm and a half, of the Ung. Hydrarg. fort. every day; and this was continued until the mouth became very sore; but with no effect upon the testicle. The mercury was therefore given up, and decoction of bark with iodide of potassium internally substituted. By and by, an ointment composed as follows:—

R. Potass. Iodid. ʒj. Unguent. Hydr. fort. ʒj. Unguent. Cetacei, ʒj.

was spread on lint, and laid over the affected testicle every night; and he had full diet.

Under this plan the right testicle became of the natural size, and the general health good, so that the patient declared he felt as well as ever he did in his life. Discharged.

Examined about a month afterwards, this man was found to have continued in excellent health, and had been doing his duty. The right testicle feels partially atrophied, but it is sensible to pressure, and is only half the size of the left, which is of natural dimensions.

REMARKS.—The question of most importance in the foregoing case appears to me to be the following:—

What was the nature of the disease? Was it "hernia humoralis" of the right testicle, which the man laboured under when admitted into hospital at Dover, in September 1842? Or was it a case of "hernia humoralis" with "acute rheumatism," as entered in the register, in January 1843? For my own part, after repeated perusals of the case, and judging from the effect of the treatment, the present state of the right testicle, the man's positively stating (and he bears a good character) that he never had any gonorrhœa when in hospital at Dover—the fact of the left testicle becoming attacked in a manner so similar to the right a year afterwards—both attacks having been ushered in by what are considered as well-marked symptoms of "venereal hectic;"—from all those circumstances, and from thinking over the case with as much attention as I am capable of giving, I confess I look upon it as "venereal sarcocele" attacking the right testicle at Dover, in September 1842, eleven months after the primary sore on the penis had been healed at Cork (Oct. 1841). The "tumor (abscess) over lower third of fibula of right leg," which was so decidedly benefitted by blistering, and which did not proceed to suppuration, I believe to have been a "venereal node;" and lastly, the affection of the "left testicle," for which the man was admitted into hospital by me in February 1844, was, I think, also "venereal sarcocele;" very much resembling the attack, as it is reported to have occurred, in the right testicle, with the exception that the latter was not accompanied by the effusion of any fluid into the cavity of the tunica vaginalis.

A year elapsed between the healing of the primary sore on the penis at Cork, and the attack in the right testicle at Dover; and another year intervened from the time the man was discharged from hospital for the affection

of the right testicle, February 1843, to the period of his admission for that of the left, viz. Feb. 1844. But this assuredly does not militate against the idea of his complaint being secondary syphilis; as many cases might be adduced in support of the opinion that secondary syphilitic affections vary as much in the periods as the modes of their attack. The immortal Duypuytren states (if I recollect aright) in his "*Leçons Orales*," that one of the symptoms most to be relied upon of an affection of the testicle being "venereal," is its remaining in one testicle for six months, a year, or a year and a half, then leaving it and suddenly attacking the other* ; I would also refer particularly to a case by Dr. Moorehead of Tullamore, published in the "*Dublin Medical Press*" of the 4th of October, 1843, under the title of "*Cachexia Syphiloidea*," which strongly resembles the one I have just described, and which I think was certainly secondary syphilis.

With regard to the hoarseness and cough complained of by Stubbs on his admission into hospital at Brecon in February 1844, I look upon them to have been a form of the then prevalent "*Influenza*," having admitted other cases into hospital at the same time, which were affected in precisely a similar manner, and got well under similar treatment. If I were asked to which of the remedies the removal of the disease in the testis was to be ascribed, I should say that I really do not feel myself competent to answer the question. But I may add, that I have known a case of "venereal testicle" occurring in a person in whom it had returned again and again after the administration of more than one course of mercury for its cure (which it is but fair, however, to say, was not used in the most approved manner), cured by a decoction of cinchona internally, with cold shower baths, and hydriodate of potass ointment applied to the diseased gland externally.

THOMAS MOORE SUNTER,

CASE OF HYDATIDS OF THE LIVER
AND ABDOMEN.

ANALYSIS OF THE HYDATIC FLUID.

To the Editor of the Medical Gazette.

SIR,

If you deem the following case worthy of a place in your journal, you will oblige me by inserting it.

Your obedient servant,

J. W. GRIFFITH, M.D. F.L.S.

Senior Physician to the Finsbury Dispensary.

July 13, 1844.

Maria Worledge, *æt.* 42, was admitted under my care as a Dispensary patient, on the 5th of June, 1844. Her previous history, as well as I could make it out, (for it is generally very difficult to obtain anything like accurate information from these patients concerning their early history) was as follows:—When quite young she had typhus fever; otherwise, up to the time of her marriage, which took place at the age of 21, she enjoyed perfect health. Her father died of consumption; her mother is still alive, and in good health. Nothing similar to her ailment has ever appeared in any of her relatives. She miscarried about five months after marriage; since then, until the last three months, the catamenia have always appeared regularly. She never had jaundice. Her husband recollects remarking at the time of marriage a slight prominence at the epigastrium, slightly towards the right side. She afterwards noticed this herself, and about three years after marriage her feet and legs began to swell; the face remained natural; the tumor then became very hard and painful, but there was no redness. Shortly after this, having suffered extremely from dyspnœa, great pain in the abdomen without fever, and great enlargement, the most prominent point of the tumor, which was at the umbilicus, burst, and a "pail-full" of a peculiar gelatinous matter, some of which was very offensive, was discharged. A sanious matter continued to issue from this opening, and occasionally long pieces of solid matter projected through it, some of which were discharged, others remained blocking it up; the latter were frequently cut off, without producing any pain.

After this, a slight discharge continued to ooze from the aperture, and she went to the Bermudas, where she re-

mained for eight years. Three years after this, the epigastric and right hypochondriac region again swelled, became very painful, and one point in the right hypochondrium became very red and prominent; it was opened, when blood and pus came out. At this time the umbilical aperture had healed.

When I first saw her, the face was pale and yellowish; the conjunctivæ were, however, white; the whole face slightly puffy, particularly the left eyelid (the left was the side on which she constantly lay). She had a constant hacking cough; the breathing was short and quick; the abdomen much enlarged, and its walls œdematous; there was indistinct fluctuation in the lower part: the most prominent portion, which was on the right side of the hypogastric region, felt slightly elastic. Both the apertures from which the peculiar matters had been discharged were open, and the surrounding parts of the abdomen were slightly retracted at those parts. The whole abdomen was dull on percussion, except the upper and back part, especially the right, where it was more resonant. The stools were of various colours, green, yellow, and white. The urine was tolerably copious, pale and albuminous. The feet and legs were much swollen. There was no fever, thirst, nor quickened pulse; the tongue was slightly furred. The chest was quite clear on percussion, except at the posterior and inferior parts, especially on the left side, where it was dull; the respiration was puerile all over the chest, but towards the lower and back part were various rhonchi, and quite low down behind there was a sub-crepitant rhonchus. She remained under treatment for a month, during which time purgatives, diaphoretics, iodide of potassium, elaterium, and diuretics, were had recourse to; the dropsical symptoms, however, remained the same, until 24 hours before death, when, as usual in such cases, they almost entirely disappeared; she died comatose and convulsed.

The abdomen only was examined after death. The examination of the liver was found very difficult, the whole proper substance of the right lobe having been entirely destroyed, and a thick yellowish cartilaginous mass, with occasionally a piece of bone, was all that remained; this was anterior to

the diaphragm and anterior abdominal walls. The gall-bladder was situated on the under part of this mass, and was filled with healthy bile. Imbedded in the cartilaginous mass just spoken of, was a large cyst, capable of containing from a pint to a pint and a half; this was filled with hydatids of various sizes. The left hepatic lobe was of the ordinary size, and free from hydatids; the portal venous system was filled with blood; the intra-lobular veins were empty. The spleen was softened, resembling currant-jelly, and free from hydatids. The abdomen contained a considerable quantity of fluid, and its walls were much infiltrated, so that they were very thick. Imbedded in the left side of the great omentum was found a hard mass, composed of three spherical nodules, each about one inch in diameter, firmly united; these were filled with hydatids. Another tumor, as large as an orange, was found between the peritoneum and abdominal muscles in the right side of the umbilical region; this was also filled with hydatids. The kidneys were very small and extensively granular, and throughout their substance were found simple cysts filled with fluid. At the anterior and inferior part of the peritoneum were found some small tubercles of ossaceous hardness, and about the size of small peas, but containing no hydatids. The blood which was examined during life contained a large quantity of urea.

The walls of the cysts containing the hydatids were of various thicknesses; those of the larger were very thin, those of the smaller very thick and white, resembling cartilage*. Those of the hydatids were perfectly transparent, soft, and gelatinous, exhibiting no trace of structure. The hydatids were perfectly free and unattached, and within each was contained a perfectly transparent liquid. It had a sp. gr. of 1.008; was slightly coagulated by heat and nitric acid; contained merely a trace of fat. 1000 parts left 15 of solid extract, consisting principally of chloride of sodium; it was very deliquescent. It left 85 per cent. of chloride of sodium, a little carbonate and sulphate of soda, and a trace of phosphate of lime, and 65 of albuminous extractive matter. It contained neither cholesterine nor alkaline phosphate. The

* They were not, however, true cartilage, for they were made up of parallel fibres.

gelatinous coating of the hydatids appeared to be of a peculiar nature; when dried it left a brownish residue, which dissolved by boiling in muriatic acid with a deep brown colour, but no precipitate was caused on adding an alkali. When moist, the membrane was dissolved by muriatic and nitric acids, but the solutions were not precipitated by ferrocyanide of potassium nor by tincture of galls. When boiled for some time in water, none was dissolved, for the solution was neither precipitated by tannic nor nitric acids, nor did the solution gelatinise on cooling. When boiled with solution of potash, the dried membrane was dissolved, and the solution rendered brown, but neither was sulphuretted hydrogen evolved, nor any precipitate formed on the addition of an acid.

ON THE PATHOLOGY AND TREATMENT OF OVARIAN DISEASES;

WITH CASES.

By DR. SAMUEL J. JEAFFRESON,

Physician to the Chelsea, Brompton, and Belgrave Dispensary, &c.

CASE I.—Ovarian tumor, partly solid, partly fluid, duration of twenty-two years. General health not much impaired—chief inconvenience from the bulk of the tumor.

November 25, 1838.—I was consulted by Miss G., between 40 and 43 years of age, for an enlargement of the abdomen, which she suspected to be dropsical. I found the abdominal cavity occupied by an enormous tumor, which appeared uniformly solid and hard excepting at its lower portions, where there was perceptible fluctuation. The tumor, which was moveable, did not appear to have contracted any adhesions to the abdominal walls; it pushed aside the descending colon, which was much loaded with flatus. The size of the abdomen was that seen from the seventh to the eighth month of pregnancy.

The general health was but little impaired, except that she was beginning to experience considerable inconvenience from the weight and bulk of the tumor, which, by its pressure, caused derangement of the abdominal viscera, in the shape of dyspepsia, flatus, and constipa-

tion. The catamenia, previously regular, had ceased within a year of my being consulted. The tumor had been first perceived sixteen years ago; but did not appear to occupy one side of the abdomen more than the other. Its increase of bulk had been very gradual.

I prescribed with a view to relieve the dyspeptic symptoms, constipation, and flatulence; and also ordered her the liquor potassæ; and the ointment of iodide of potassium to be rubbed into the abdomen. She experienced speedy relief to her more urgent symptoms from the former part of the treatment; the latter she has continued at intervals, I believe, ever since, and she is now, six years nearly from my first interview, even better in her general health than at that period. I have not latterly had any opportunity of examining the abdomen, but she assures me that it "has not at all increased in size." This patient had, previously to my seeing her, frequently submitted to courses of medicine, with a view to relieving or curing her disease.

CASE II.—A similar case, only larger, and of twenty-five years' duration.

Mrs. P. is now about 50 years of age; she was married in early life, and never had any family. For many years past I have been in the habit of seeing this lady from time to time. The abdomen is at present *enormously* distended, and has been in this state for many years; and she experiences great inconvenience from the weight and bulk of the tumor, which is partly solid, partly fluid, and appears divisible into three great masses; being considerably larger on the right side. This patient is also labouring under extensive enlargement of the thyroid gland, which is also partly fluid and partly solid, and divisible into three great portions or masses.

The general health, even at the present advanced period of the disease, is not more impaired than may be accounted for from the great bulk and mechanical inconvenience arising from the presence of the tumors of the body and thyroid gland.

It is now twenty-five years since the swelling was first perceived; it came on with violent pain in the lower part of the abdomen, and stoppage of urine;

it first made its appearance on the right, and then on the left side.

This patient has frequently undergone various courses of treatment, under the advice of many medical men of high character, but without any appreciable advantage either in diminishing or arresting the growth of the tumors.

It would not be difficult, either from the resources of my own personal observation, or by reference to the practice or writings of other medical men, to bring forward numerous instances of ovarian disease, similar to the above, in which the tumors, partly solid, partly fluid, had existed for many years, with little further inconvenience to the general health than was due to their bulk.

CASE III.—Chronic ovarian disease—tumor apparently entirely fluid—has existed ten years. Paracentesis performed three times within the last six years. General health not much impaired.

In August 1838, I first saw Mrs. S., in consultation with my friend Dr. Bland. Her age was about 45; she had never had any family. The catamenia, which had always been regular, had ceased to appear for some years. There was great distension of the abdomen, of a pretty uniform shape, apparently entirely fluid, and fluctuating. There was some emaciation. The general health, although not more impaired than might be considered due to the bulk of the abdominal swelling, was beginning to break. The disease was first perceived four years ago; it did not appear to originate in either side of the abdomen, but was preceded and accompanied by severe dragging pain, extending from the right hypochondriac to the umbilical and epigastric regions. She has umbilical hernia of many years' standing, which she says, "often increases in size from coughing, and is filled with wind."

When placed perfectly flat on her back, the fluid occupies the upper portion of the abdomen, the colon on either side remaining beneath the fluid, and perfectly resonant on percussion. There has never been any anasarca, no signs of diseased heart or lungs, and she never was jaundiced. The urine copious and natural. She has been

subjected to every kind of treatment, often to the injury of her general health, without even the slightest diminution of the abdominal swelling, which, on the contrary, has gradually and steadily increased.

I considered the disease ovarian dropsy, and as she was beginning to experience great inconvenience, both to her health and comfort, from the enormous size of the abdomen, I suggested to her the propriety of submitting to the operation of paracentesis; which was performed on the 21st of August, a week after my first visit, by Mr. Eaton. Upwards of three gallons of clear, straw-coloured, somewhat gelatinous fluid were evacuated. This fluid continued clear to the last, but became a little more gelatinous; there was a copious white deposit on the addition of nitric acid.

Our patient went on uniformly well; suffering only occasional "crampy pains" of the abdomen, and some weakness of the loins; she was soon, however, out and about; her general health was very greatly relieved by the operation, and she enjoyed excellent health in every way. On careful examination of the abdomen, no tumor could be anywhere discovered, and there appeared nothing unnatural in the hepatic region.

The fluid very gradually re-accumulated, and at the end of two years she was again tapped, with the same results in every respect; she was again restored to health and comfort, and at the end of two years was again tapped; but on this occasion the amount of fluid accumulated was considerably less. The result of the third operation was equally satisfactory, and she is now, at the expiration of two more years, beginning to be in a state soon to require its repetition for the fourth time.

This case may be said to be less common than the two former, although by no means of very rare occurrence. In respect of the very satisfactory relief obtained on each occasion of tapping, and the very gradual reaccumulation of the fluid, rendering a repetition of the operation necessary at intervals so far removed as two years, the case may be said to have proved a very favourable one for this mode of treatment. I may remark that, for a long time subsequently to the first operation, this lady took, by my advice,

the iodide of potassium and liq. potassæ separately or combined; the interval, however, of the reaccumulation having been the same on subsequent occasions as at the first, but a small part of the favourable progress of the case can, I think, be attributed to this treatment.

CASE IV.—Ovarian tumor, partly solid, partly fluid. Paracentesis. Death within a year from the first manifest symptoms of the disease. Post-mortem appearances.

E. R., a single woman, æt. 21, first came under the professional care of my friend Mr. Ferneley on the 21st of June, 1840. The principal feature of the case was retention of urine, the patient not having evacuated the bladder for two days. The bowels habitually costive. The catamenia, irregular, scanty, and pale. The bladder was felt to be much distended, and there was a degree of hysterical manner about the patient. She was much relieved by the use of the catheter, and purgatives combined with hyoscyamus; still, however, some tenderness of the abdomen remained. Shortly after this period, a small, hard, moveable tumor, about the size of a walnut, was perceived above the pubes, rather to the left of the median line. This gradually increased in size, was always painful and tender, the pain much increasing about the monthly period, which became more and more irregular and scanty.

The treatment consisted in occasional local abstractions of blood, salines, with hyoscyamus, mercurial alteratives, aperients, and emollient enemata; and subsequently of iodine used both internally and externally.

In the autumn of 1840, the size and shape of the abdominal enlargement was such as, combined with the general symptoms, to lead Mr. Ferneley and myself to entertain some doubts as to our patient having deceived us respecting the state of the catamenia, and the possibility of her being pregnant. A more careful examination, however, removed this doubt. The tumefaction of the abdomen gradually increased, and evidently became softer in parts; the general health became more impaired, and by the summer of 1841 the distension had become so great as to produce so much distress, and such urgent dyspnoea, as to make

the patient anxious to obtain some relief by the operation of paracentesis. At this time the tumor appeared to be partly solid and partly fluid; adherent in some parts to the parietes of the abdomen, where the cavity appeared to be further distended by ascitic effusion. The general health had become so much broken, mainly, perhaps, from the long continuance of what had been in this case a very painful as well as distressing ailment, that there did not appear any hope of life being much prolonged, not perhaps beyond a few weeks or a couple of months, without some relief being afforded.

On June 5th, 1841, Mr. Ferneley performed the operation of paracentesis, and about four gallons of fluid were drawn off.

The immediate effect of the paracentesis was to afford considerable relief to the dyspnoea. About two days after the operation the wound made by the trochar (which probably never healed) allowed of the discharge of a considerable quantity of fluid, similar to that which had been removed by the operation. She continued to become more enfeebled, a low form of peritonitis supervened, and she sunk on the 17th of June, twelve days after the operation.

The post-mortem examination, which was conducted by Mr. Ferneley and myself, about thirty hours after death, showed a large tumor of the left ovary, adherent to the peritoneum a little above the umbilicus, on the right side, and in its posterior aspect: on attempting to break through the adhesions, the tumor, which was much softened and completely disorganized in parts, gave way in its lower and posterior portion, and discharged a considerable quantity of very offensive matter, somewhat of a puriform appearance, in which flocculi of cheesy matter abounded. The right ovary was slightly enlarged, as was also the uterus. A further examination of the left ovary presented the appearance of cysts containing matters in various degrees of softening or fluidity, and that of the right presented the appearances to be described in the relation of Case VI. The peritoneum presented signs of pretty general inflammation of a low character.

CASE V.—*Ovarian tumor, very rapid in its growth, softening and bursting*

spontaneously in the recto-vaginal septum—perfect cure.

On June 19th, 1839, I visited Mrs. P., about 38 years of age, in consultation with Mr. Smith. Mr. S. having been unavoidably detained for some time, I was, after waiting a long time, ushered into our patient's room. I found her labouring apparently under ileus, with some peritoneal inflammation. On placing my hand on the abdomen, however, I was surprised to find the lower portion of it occupied by a tumor in size and uniformly resembling the uterus at about the sixth month of pregnancy, but of universally unyielding hardness; the whole anterior and lateral regions were perfectly dull on percussion, and it was only quite low down on either side that the resonance of the bowels could be detected.

She could give no distinct account of the origin of the tumor; "she thought that she had had some enlargement of the body for three months past, but as it had come on without any pain or other inconvenience, she had paid little attention to it." For a month or six weeks past her neighbours had remarked her increased size, which had by them been attributed to pregnancy; she had been married about twelve months. The catamenia had continued regular, and there was no sympathetic affection of the stomach or breasts.

She had been ill three days: the symptoms were those of ileus and slight peritonitis, with moderate febrile disturbance.

Till my visit she had never suspected that she laboured under any distinct tumor of the abdomen. Her present attack was attributed by her to severe jolting in the course of a long journey over rough cross roads.

Mr. Smith and myself regarded the tumor as ovarian; we considered it an awkward complication of her other symptoms, but determined to treat the ileus and inflammation, whether of the peritoneum or tumor itself, on ordinary principles, hoping that if those symptoms yielded, our patient might remain in at least as good a position as before her attack.

Venesection was performed, but the patient, who appeared nervous about it, having never before been bled, soon became faint, and but little blood was obtained. Calomel and opium, leeches,

aperients, aperient enemata, soothing fomentations, &c., constituted the remaining part of our treatment.

On the 20th and 22d, I saw Mrs. P. again; she went on favourably; the bowels were acting freely under the influence of medicine, and all symptoms of ileus had disappeared, when, on the 25th, I was requested to see her again in consequence of the persistence of considerable pain and tenderness apparently in the tumor, and especially in its left and lower portion. It had perceptibly increased in size, and continued to be *intensely* hard. Leeches, aperients, soothing fomentations, suppositories, carminative enemata, and finally mercurials, constituted the chief part of the treatment. In spite of all the measures adopted, the tumor rapidly increased in size, and appeared to be getting somewhat more yielding, but always remained uniform in shape and feeling as regarded its different parts. Sometimes came a day on which the patient was free from pain, and comfortable, and then two or three when the pain and distress were increased; great and troublesome flatulence supervened, and latterly incessant vomiting.

On the 11th of July we had the further advantage of Dr. Turner's assistance; by this time the abdomen had become as much distended as I think I ever witnessed either in ascites or ovarian dropsy, and the mechanical impediment thus offered to respiration, &c., was equally urgent as in the worst form of these diseases.

The character of the tumor was the same as before, and it was equally dull on percussion in all directions; it had, however, to my mind, become evidently more yielding. The pain was very great at times, especially on moving. Nothing at all was borne on the stomach; sitting up at all induced faintness.

Large doses of hydrocyanic acid were given to allay the irritability of the stomach. Opiates, the local application of iodine, and iodide of potassium in the shape of ointment, and the internal administration of these drugs in solution, whenever the stomach could be brought to retain them, constituted the chief treatment adopted. In a fortnight from this time we fancied we could detect obscure fluctuation in the tumor; the patient continued to

labour for upwards of a month under the greatest sufferings and distress, and was in the utmost peril of her life, when, on or about the 10th of August, without her having previously experienced pain or other sensation in that situation, the tumor gave way in the recto-vaginal septum, and prodigious quantities of fluid escaped in part from the rectum, in part from the vagina. The matter which was thus evacuated was highly offensive, and appeared like a mixture of serous fluid, pus, and flocculi, probably of lymph: as a large portion escaped in the bed, and some in the night-pan, &c., it was impossible to ascertain the exact quantity which was passed. The immediate effect of this escape of matter was to induce some little faintness, and considerable alarm and anxiety; this, however, was speedily followed by relief to all her symptoms: on the second or third day afterwards there was a good deal of pain experienced, followed by another copious discharge of a similar character; from this time the patient continued to do uniformly well. She was soon sitting up, and down stairs. The openings, which had been distinctly felt by the finger, both in the rectum and vagina healed up, as there was no further discharge. The abdomen became quite natural in size and feeling, and continues so to the present time; the patient enjoying excellent health.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

A Letter to Professor Liebig on some Misrepresentations contained in the second edition of his work entitled, "Animal Chemistry." By GEORGE KEMP, M.D.

THE author states that while experimenting at Giessen, he ascertained that the contents of the gall-bladder contained two bodies; one rich in nitrogen, the other containing no nitrogen at all, or in quantity so small as hardly to be estimated by ordinary means. The former is the mucus of the gall-bladder; the latter, the main subject of his present inquiry, is the biliary fluid, properly so called. He further determined that the soda found in the bile is not uncombined.

The author next proceeds to charge the celebrated Professor of Giessen with having given "a garbled and mutilated account" of the record of his analyses of bile, as published in *Erdmann's Journal*. For it would appear that Dr. Kemp had instituted two series of analytical researches; one, as to the quantity of carbon and hydrogen, the other as to the entire composition of the fluid.

"The two first of these have been selected by you as expressive of the constitution of the bile; and to them you have attached the amount of nitrogen, oxygen, soda, and chloride of sodium, elicited by two subsequent analyses" (p. 10.)

"Now, Sir, the most superficial reader will perceive, that, by attaching the chloride of sodium, found in my last experiments, to the two first analyses, you have proportionably diminished the quantity of organic matter, and thus you have laid yourself open to the exposure of an inaccuracy which a person, disposed to indulge freely in *ex cathedra* statements, should be scrupulously careful to avoid. In order to show that this misstatement has not arisen from any confusion in my manner of publishing the results, I shall include the passage alluded to in an Appendix. From the above it will be seen how utterly valueless your representations of my analyses are rendered by your attaching the determination of the inorganic portion of one analysis to the organic portion of another; in fact, the analyses 1.2.3. can no more give an insight into the composition of the bile, than the hydrogen and carbon determinations of Messrs. Enderlin, Theyer, and Schlosser" (p. 12).

He then proceeds to show that Professor Liebig's attempt to identify the composition of the substance combined with soda in the bile with that of choleic acid, as furnished by Demarçay, is untenable, because it is proved by calculation "that the organic body in the bile contains one per cent. less of carbon than the choleic acid of Demarçay, and is, therefore, very unlikely to be that body" (p. 14.)

Touching the Professor's next remark: "If we assume that the soda in the ashes of bile is in the form of neutral carbonate, then 100 parts of the organic part of purified bile contains

64.9 of carbon." Dr. Kemp says, "your calculation is again wrong, for the lowest quantity of carbon which I obtained, viz. 58.46 per cent. (supposing the soda remaining behind as Na O, CO^2) would give more than 66 per cent. instead of 64.9, as stated in your work, page 337. I mean nothing offensive, but would really recommend you, in future, to take care that your arithmetic is correct; as errors of this kind not only unnecessarily involve the subject, but waste time in their correction which could be more usefully employed" (p. 15).

Now we must confess that we do not admire the tone in which this censure is conveyed, and which generally pervades the pamphlet before us; and, with all deference to Dr. Kemp, we humbly suggest that the error in question may possibly be one of the press, inasmuch as $58.46 + 11.00 = 69.46$, the printer having inadvertently put down 64.9 instead of 69.4.

The author next introduces the results of a rather elaborate examination of various kinds of bile. The first is human bile, taken about eight hours after death from a male adult who died of *delirium tremens*. The following are its physical characters: "Colour; deep brownish yellow, without the olive tint which characterizes ox-bile, and leaving a bright yellow stain on the skin, which was washed off with difficulty. Taste; intensely bitter, without the pleasant aromatic flavour of ox-bile. Specific gravity; not examined, as it was desirable to keep as much as possible for analysis; from the quantity of solid matter obtained on evaporation, however, it was inferred that no considerable difference existed between this fluid and the ox-bile in this respect. [The sp. gr. may be examined and determined exactly, without wasting a particle of the bile.] No alkaline reaction was produced on turmeric paper; and here I must mention, that, in examining the human bile and that of carnivorous animals, an error is very easily made with reference to its neutral condition, on account of the intenseness of the colour. The test-paper, after being moistened with water, should be treated with the fluid and again carefully washed; in most cases, when the paper, thus used, has been allowed to dry, a slight streak of brown colouring matter will be observed as a

line of demarcation between the moistened and dry portion; but this is merely due to capillary attraction and the difficulty of removing every trace of the bile by washing. I think, however, that, with these precautions, the human bile, in its perfectly healthy and fresh state, will be found invariably neutral; though I by no means pledge myself to the *converse* opinion. The analysis of this secretion is attended with considerable difficulty, on account of the rapidity with which the solid matter, obtained by evaporation, attracts moisture; this is also the case with the ox-bile, but not in so remarkable a degree."

Having precipitated the mucus by means of alcohol, the remaining biliary fluid evaporated to dryness, and subjected to ultimate analysis, yielded in three experiments:

1. Carbon = 68.4 per cent.
Hydrogen = 10.13 per cent.
2. Carbon = 67.4 per cent.
Hydrogen = 9.6 per cent.
3. Carbon = 68.3 per cent.
Hydrogen = 10.0 per cent.

The combustion in number 2, he observes, was evidently incomplete. The nitrogen obtained by the direct method = 3.44 per cent.; by Wills's method = 3.50 per cent.

The bile of several species of monkey examined was without exception neutral; but although the quantity was so small that no available analysis could be made, they were decidedly confirmatory of the fact, "that the bile is essentially composed of an electro-negative body in chemical combination with one or more inorganic bases."

Having obtained the above results, Dr. Kemp directed his attention to the bile of carnivorous animals. The following are the physical characters of that of the tiger: "colour much brighter than the human bile, but not tinging the skin so deeply;—from the quantity of mucus diffused through it, the fluid was opaque. The mucus presented a totally different appearance from the mucus of the gall-bladder of the ox or human being, and has yet to be examined. Smell; peculiarly strong and urinous. Taste; nauseous, intensely bitter, and not leaving the agreeable after-flavour of ox-bile. The fluid was perfectly neutral."

One striking feature, he observes, of bile in carnivorous animals in every

case, is, that it contains no chloride of sodium. It is also singular that the base should be soda. By ultimate analysis it afforded:—

Carbon = 69.6 per cent.
Hydrogen = 11.8 per cent.

The nitrogen was estimated by the direct method, and amounted to 6 per cent.

Having now met with a species of bile containing 69 per cent. of carbon, it seemed a fair opportunity for deciding whether the secretion undergoes any modification by treatment with metallic oxides. A portion was therefore treated with basic acetate of lead in the usual manner. Deducting the inorganic matter from the substance formed by means of oxide of lead, Dr. Kemp obtained:—

Carbon = 62.1 per cent.
Hydrogen = 9.3 per cent.

Now the choleic acid of Demarçay contains:—

Carbon = 63.5 per cent.
Hydrogen = 9.3 per cent.

"With these facts, I do not see how it is possible to resist the conviction, that this body is the choleic acid of Demarçay in combination with oxide of lead; and this being admitted, we must also conclude, in the most unequivocal manner, that *the body contained in this species of bile at least is not choleic acid*; its equivalent weight, its physical relations to other bodies, its quantity of carbon and hydrogen per cent., carry with them a weight of evidence irresistible to a mind not altogether paralysed by prepossession, that it is as different a body from choleic acid as we can conceive."

Leopard's bile stands next in order of investigation. It was procured about eight hours after the animal's death, and possessed the same physical characters as the tiger's bile. It was perfectly neutral. The preparation for ultimate analysis was the same as above; that is to say, the bile was first freed from mucus by alcohol, then from fatty matters by ether, the dry mass treated with alcohol '840, to separate all salts insoluble in that menstruum, and the substance for analysis obtained from the filtered fluid in the usual way. It yielded upon combustion:—

Carbon = 59.5 per cent.
Hydrogen = 10.0 per cent.

The nitrogen amounted to 4·4 per cent., or 4·6 deducting the ash.

Subjoined is a tabular view of the above analyses :—

INORGANIC PORTION.

	*Ox-bile. ^a	†Human Bile. ^b	Tiger's Bile. ^b	Leopard's Bile. ^b
Soda 6,53 .	. 6,6 .	. 5,2 .	. 4,6
Chloride of Sodium .	. 0,37 .	. 1,87 .		

ORGANIC PORTION.

	Ox-bile. ^a		Human Bile. ^b		Tiger's Bile. ^b		Leopard's Bile. ^b	
	I.	II.	I.	II.	Lead Salt.		I.	II.
Carbon . .	64,60	64,85	68,4	68,3	69,6	62,1	59,8	59,5
Hydrogen .	9,62	9,40	10,13	10,00	11,8	9,3	9,49	10,0
Nitrogen .	3,40	3,40	3,44	3,50	6,0		4,60	4,60
Oxygen .	22,38	22,35	18,03	18,2	12,60		26,11	25,90
	100,00	100,00	100,00	100,00	100,00	100,00	100,00	100,00

There is one point which somewhat staggers us in reference to the above analyses, namely, the great difference in the proportion of carbon, nearly 10 per cent., between the bile of the tiger and that of the leopard, two animals so closely allied in conformation, in habits, and manner of living.

At page 32 our author returns fresh to the charge, and asserts that the Professor's formula for choleic acid is merely a deduction from an hypothesis, and contrary to the facts as elicited by analysis.

"The formula you give for the choleic acid is $C_{74}H_{104}N_2O_{22}$ = 19142,62. The formula for two equivalents of Demarcay's acid is $C_{84}H_{112}N_2O_{24}$ = 9720,92. Now any person accustomed to the least practical research in *organic chemistry*, must be aware that such a difference in combining weight, in bodies even nearly resembling each other in the results of their analysis, reduced to a per centage, cannot by any possibility characterize the same body. Either the analyses of Demarcay and Dumas are false, and in that case your formula grounded on no analysis at all (for none other than Demarcay and Dumas have ever been made), or else your formula has been constructed in direct opposition to the facts of the case. Still further; on analysing the organic

portion of the ox-bile, united with soda, the combining weight was found = 5644, and it matters not for our purpose whether this number represents half or twice the true equivalent, or the *actual equivalent itself*; no kind of violence can bring it near the combining weight of Demarcay's acid. Deducing a formula in the usual manner, and considering the bile as a neutral salt, an assumption much more likely to be true, as we shall presently see, than any other, we find $C_{44}H_{62}N_2O_{11}$ as representing the organic body. I repeat it again; multiply the per centage, found by me in the ox-bile, by the atomic or equivalent weight already found, 5644, and (until a new atomic weight for carbon, differing widely from any we at present possess, be (given you must come to the number C_{44} , or some multiple or divisor of the same by whole numbers. But not to depend upon mere reasoning, let us refer to the facts, as stated by you in pages 342 and 343 of the second edition of your work in English;—a record of analyses, on page 342, is given as the results obtained by Messrs. Theyer and Schlosser, and, on page 343, of two made in the laboratory at Giessen, and, subsequently, recorded in *Erdmann's Journal* by myself."

The recent researches of Theyer and Schlosser upon the bile are adduced in corroboration of the fact that the body in question can neither be the choleic acid of Demarcay nor the hypothetical choleic acid of Liebig; the former requires 42 equivalents of carbon, the

* The analyses marked * were made in the laboratory at Giessen.

† The analyses marked † were, by the kind permission of Professor Cumming, made in the laboratory of the University of Cambridge.

§ Berzelius, B. p. 8. 267.

|| Depending on public records.

latter 38 equivalents. "Your hypothetical soda salt of the bile, on which you found your theories, consists of C_{88} ; even the analysis of MM. Theyer and Schlosser is so obstinate as to force you up to C_{44} : mine, checked, controlled, counter-controlled, and ready to be controlled again, are unfortunate enough to arrive at C_{48} " (p. 36).

At page 39 some contradictory statements are quoted relative to the identity of bile with choleate of soda, from pages 333 and 342 of the "Animal Chemistry."

We conclude our notice by subjoining Dr. Kemp's approximative formulæ of the three kinds of bile.

Graminivorous bile = $C_{48} H_{42} N O_{18}$
 Omnivorous bile = $C_{50} H_{46} N O_{10}$
 Carnivorous bile = $C_{64} H_{61} N_2 O_{22}$

We would again enter our formal protest against the violent tone manifested throughout this pamphlet, and earnestly recommend the author, when he next enters the lists of controversy, to do so as one not "*fervens difficili bile.*"

ON THE

FUNCTIONS OF THE TROCHLEARIS MUSCLE OF THE EYE.

"Miss.—Madam, one of your lappets is longer than t'other.

"Lady Answerall.—Well, no matter; they that ride on a trotting horse will never perceive it."

SWIFT'S POLITE CONVERSATION.

THE difficulty of obtaining an accurate view through a telescope held in the hand is a matter of common experience, although that method of support may suffice for a superficial observation. In like manner, when we are walking or riding, large objects are seen distinctly enough for ordinary purposes; but for an attentive examination we are obliged to stand still. But if to this end it be necessary that the whole body should be at rest, how much more so is it that the eye itself should possess the means of quiescence. In using any voluntary muscle or set of muscles, it must be remembered that the nervous influence is not transmitted in a constant and uniform current, and hence the difficulty we have to hold any thing

motionless. If, for example, we hold a weight suspended by a string, our utmost efforts cannot bring it to a state of perfect repose, however it may be made by great practice to approximate to that state. But a very small degree of friction or adhesion enables us at once to accomplish the object without difficulty. Thus, by reflecting the cord over a pulley, or the back of a chair, the weight no longer derives a tendency to motion from our attempts to restrain it, but soon becomes stationary.

With respect to the oculo-motory apparatus, the comparison I would draw would be obvious, were the functions of the nerves which supply it not still matter of controversy.

The view I have long entertained on this subject, and which I would not obtrude upon you if I did not think it original, is that the trochlea is an adhesive apparatus, the tendon passing over it being analogous to the cord in the foregoing illustration, while the hand represents the inferior oblique (a voluntary muscle), and the musculus obliquus superior the gravitating principle, its function being to exercise a constant tension, like the sphincters.

To suppose the oblique muscles in any way a cause of motion of the eyes, belongs to the error of admitting too many causes; since the combined action of two adjacent recti muscles is sufficient of itself to account for every motion, except rotation on the axis of vision, the existence of which is problematical. As the mariner's compass, swung upon two pairs of trunnions fixed at right angles to each other, is capable of receiving every possible direction, so may we conceive of the motions of the eye in respect of two axes corresponding to the recti muscles. For did the side muscles alone exist, the motion of the eye would be horizontal, and the axis vertical. Were, on the contrary, the rectus supe-

rior and r. inferior the only muscles, the eye would move in a perpendicular plane, and the axis of motion would be horizontal; whilst the two conjoined render every intermediate motion and direction practicable.

That the eye rotates on the axis of vision I conceive to be a fallacy; and though, according to Professor Valentin's experiment (of fixing upon some prominent blood-vessel in the conjunctiva, and causing the person experimented upon to incline his head towards his shoulders alternately whilst he keeps his eye fixed upon the same object), though the eye have the appearance of rotating, and especially upon a quick wagging of the head; yet this may proceed from the orbit itself not moving exactly round the axis of vision; whence there is a constant disturbance of the recti muscles; and until these are at rest, and have attained their necessary tension, the proper function of the oblique muscles is suspended. But no sooner does the motion cease, however oblique the position of the head may be, than the blood-vessels observed resume their wonted place. We can roll the eye at will, *i. e.* give a curvilinear motion to the axis of vision—we can also dilate or contract the pupil mediately by a voluntary act—but we seem to have no power over rotation, either immediate or mediate, except as the result of the just cited experiment.

Motions of the eye caused by traction of the muscles in the dead body I hold to be equally fallacious evidence of the living function: first, because the other muscles have not their vital tension; and secondly, because the function of the nerve, as voluntary or automatic, can only be established by experiment on the living subject. To deny the effect of such traction would be to renounce in the same breath the view here propounded; for to imagine

the oblique muscles attached to any part of the surface of the eyeball which does not move with the motion of the eye, is impossible. Nevertheless it appears to me that they are attached to those parts of the orbit and the globe of the eye by which they are exposed to the least disturbance during its motions, and are hence the more prompt for action when the recti muscles have given it the direction wanted. It may perhaps be asked, why the involuntary function should be ascribed to the trochlear muscle rather than to the oblique inferior, since in either case the effect would be the same. The question must be answered by the fact, that the latter derives its nerve from a common source with the rectus internus and r. inferior, while the obliquus superior has a particular nerve assigned to it. The same physiologist, indeed, ascribes a more or less automic action to all the three muscles supplied by the inferior branch of the 3d pair, *viz.* the rectus internus and r. inferior, and the obliquus inferior; whilst the rectus externus supplied by the 6th, the rectus superior by a branch of the 3d, and the trochlear muscle supplied by the 4th, are in the Professor's estimation purely voluntary muscles. The fact, however, of the rectus super. and r. infer. being both furnished with branches of the same nerve, though not conclusive, affords at least, in the absence of experiment, a presumptive argument that they enjoy the same function. Further, through the necessity of parallel motion in the horizontal plane, the abducent nerve of the one eye acts in concert with the adductor branch of the other: thus making, according to the above hypothesis, a voluntary and an automatic muscle to act in unison, or the abducent muscle of one eye to be the antagonist to that of the other. But this is incompatible with the fact, that monocoli move the eye in any di-

rection, to the right and to the left, with as much ease as they who enjoy the use of both.

In a letter inserted in your journal some years since, I endeavoured to prove that the motion of the iris is not altogether automatic or reflex, but that one of its functions is to elongate the axis of the eye, in order to correct vision; and trusting these views on the nearly related subject of external motion will have novelty enough to procure them a place beside the other, I remain, Mr. Editor, your obedient servant and old correspondent,

ZETA.

CASE OF EMPYEMA:

CAN THE OPERATION OF PARACENTESIS THORACIS BE DIVESTED OF THE DANGER WHICH AT-PRESENT ATTENDS IT?

By JAMES ARNOTT, M.D. Brighton.

(For the Medical Gazette.)

WILLIAM WATERMAN, a child three years of age, of healthy constitution, was attacked with pleuritis in the first week of April last, and became a patient of the Brighton Dispensary. The disease was of ordinary character, and was judiciously treated according to the usual routine, by leeches, antimonials, blisters, &c. When the case first fell under my observation, the more acute symptoms had ceased, and the irritative fever under which the child then laboured appeared to proceed as much from the effects of one of the remedies which had been applied, viz., the blister, as from the disease. There were, besides, dyspnoea, cough, and pain in the right side, which, on percussion, was completely without sound, and on the upper part in front, and lower part all round, completely without respiratory murmur. Very little improvement took place under the treatment employed; much emaciation, with debility, ensued. Mercurials and diuretics were about this time administered, with a view of exciting the absorption of the effused fluid, but as they disturbed the functions of the digestive organs they were not persisted in, and the only medicine at last exhibited, in addition

to what the state of the bowels required, was an anodyne mixture for the distressing cough.

About the 15th of June, the dyspnoea, cough, and hectic fever, became much increased in severity. The affected side of the chest measured considerably more than the other, while the *signus* yielded by percussion, and ascertained by the stethoscope, continued as before. I now became anxious to relieve the urgent symptoms by tapping the thorax, and as the parents had witnessed the total inefficacy of all the other measures employed, there was no great difficulty in obtaining their consent. The operation, however, was not performed. On the day appointed for it a considerable change was found to have taken place, which authorised, if it did not demand, a delay of this expedient. The cough had suddenly subsided, and (according to the statement of the child's mother) immediately after nearly a cupful of yellowish matter had been expectorated or evacuated by the mouth. On examining the thorax on this occasion, instead of the right, the left side now appeared the larger, and proved to be so on admeasurement. The left side seemed likewise to be more protuberant, and more resonant on percussion, than in the natural state, as if the greater demand on its functions had increased its substance or its bulk. The right side was perfectly dull as before, excepting at the root of the lung, where, as is generally the case, even in the most extensive effusion, there was also a sound of respiration. As nausea and other disturbance of the *primæ viæ* had been caused by the anodyne lately prescribed, it was discontinued; and, excepting an occasional aperient, no medicine has been since administered. From the date of the above occurrence, there has been steady, though slow, improvement. The cough has gradually disappeared, and has only on the occasion mentioned been attended with much expectoration, although, from children generally swallowing what is coughed from the lungs, it is difficult to speak with precision on this point. There is now scarcely a symptom of disease. The child looks well, and has recovered much of its flesh, but the breathing is perhaps quicker than natural, and the pulse rather more frequent. The right side of the chest is resonant

as low as the fourth rib, and the respiratory murmur is heard above this level, though not so loudly, perhaps, as is natural, or as it is in the other side. Below the fourth rib there is neither resonance nor respiration heard; and there is evidently contraction of the lower part of the right side, with a slight bending of the spine.

OBSERVATIONS.—No point in practical medicine is more undecided than the circumstances which authorise the having recourse to the operation of paracentesis in cases of effusion within the thorax; and as the professional attention happens at present to be particularly directed to the subject, it may not be unacceptable to subjoin a few remarks on it as a commentary to the above narrative.

In the early symptoms of this case of pleuritis there was nothing worthy of notice, nor anything in the physical signs. Indeed, the history of the disease threw so much light on its nature as to render it unnecessary to attend to the less important of the signs with a view to the diagnosis. It was in the progress of cure that the case became interesting. The first step of this appeared to be the copious and sudden expectoration of pus, as if a circumscripted abscess had burst into the lung, and removed that extreme degree of pressure which impeded absorption. But the principal value of the above history is the illustration it affords of what may be effected in chronic pleuritis or empyema by the unaided efforts of nature. There may, perhaps, have been advantage from the measures resorted to in the early stage, but they nevertheless failed in removing the disease; and from the time the operation of tapping appeared expedient, no medicine whatever was exhibited, excepting an occasional aperient. It remains a question, however, whether the cure would not have been facilitated and rendered more complete by an early operation; whether the duration of the disease might not have been shortened, and the loss of function in the lower part of the right lung by long-continued compression and investment by false membranes, might not thus have been prevented. And this question respecting the propriety of endeavouring to obtain such desirable results is rendered additionally important when the

patient interested in its decision belongs to that class whose livelihood and welfare generally depend upon their possession of every bodily energy.

To compress my observations into as little space as possible, I shall state, in as many paragraphs, first, the points respecting the operation of paracentesis which are generally agreed upon, and afterwards, the points on which there still exists much discrepancy of opinion.

1. It is generally admitted that paracentesis thoracis is an operation accompanied, under all circumstances, with considerable hazard, and that this arises principally from the admission of air into the cavity of the inflamed or otherwise morbid pleura; the air acting injuriously on this, either directly, or by causing the decomposition of the purulent liquid contained between its laminæ. There can be no just comparison made, as respects the admission of air, between certain healthy tissues and the pleura in the state described.

2. That the earlier the operation is performed the less hazard there is, and the more likely is the operation, if really required, to be of service. This point was much insisted on by Dr. H. Roe, in a paper lately read before the Medico-Chirurgical Society; but the principle of the hazard being less in proportion as the operation is early, applies to every important surgical operation without exception. Every body knows, for instance, that though the operation for hernia may be performed with comparative safety while the constitution and the parts adjoining the seat of the disease are sound, yet no one would think of performing such an operation, comparatively safe though it may be, while there is much probability of removing the disease by less hazardous and milder measures*.

* If these, indeed, were only those at present generally in use, it might be a question whether the patient's interests would not be better consulted by at once liberating the intestine by the knife; but, as I have lately endeavoured to shew, in an essay on the subject, that the means in question may not only be much improved and extended, but the more efficient class of them may be used in combination, instead of the isolated manner in which they are at present employed. There is, in my opinion, as much defect in the preliminary measures adopted at present in strangulated hernia, as there would be in those preliminary to paracentesis for the removal of effusion from pleuritis, were bleeding, antimony, or mercury, totally laid aside, or employed successively instead of simultaneously. If the proper preliminary measures (as they are called) are adopted in hernia, the operation for it will, I am persuaded, be as rare as another capital operation, namely

rection, to the right and to the left, with as much ease as they who enjoy the use of both.

In a letter inserted in your journal some years since, I endeavoured to prove that the motion of the iris is not altogether automatic or reflex, but that one of its functions is to elongate the axis of the eye, in order to correct vision; and trusting these views on the nearly related subject of external motion will have novelty enough to procure them a place beside the other, I remain, Mr. Editor, your obedient servant and old correspondent,

In the early symptoms of this case of pleuritis there was nothing worthy of notice, nor anything in the physical signs. Indeed, the history of the disease threw so much light on its nature as to render it unnecessary to attend to the less important of the signs with a view to the diagnosis. It was in the progress of cure that the case became interesting. The first step of this appeared to be the copious and sudden expectoration of pus, as if a circumscribed abscess had burst into the lung, and removed that extreme degree of pressure which impeded absorption. But the principal value of the above history is the illustration it affords of what may be effected in chronic pleuritis or empyema by the unaided efforts of nature. There may, perhaps, have been advantage from the measures resorted to in the early stage, but they nevertheless failed in removing the disease; and from the time the operation of tapping appeared expedient, no medicine whatever was exhibited, excepting an occasional aperient. It remains a question, however, whether the cure would not have been facilitated and rendered more complete by an early operation; whether the duration of the disease might not have been shortened, and the loss of function in the lower part of the right lung by long-continued compression and investment by false membranes, might not thus have been prevented. And this question respecting the propriety of endeavouring to obtain such desirable results is rendered additionally important when the

patient interested in its decision belongs to that class whose livelihood and welfare generally depend upon their possession of every bodily energy.

To compress my observations into as little space as possible, I shall state, in as many paragraphs, first, the points respecting the operation of paracentesis which are generally agreed upon, and afterwards, the points on which there still exists much discrepancy of opinion.

1. It is generally admitted that paracentesis thoracis is an operation accompanied, under all circumstances, with considerable hazard, and that this arises principally from the admission of air into the cavity of the inflamed or otherwise morbid pleura; the air acting injuriously on this, either directly, or by causing the decomposition of the purulent liquid contained between its laminae. There can be no just comparison made, as respects the admission of air, between certain healthy tissues and the pleura in the state described.

2. That the earlier the operation is performed the less hazard there is, and the more likely is the operation, if really required, to be of service. This point was much insisted on by Dr. H. Roe, in a paper lately read before the Medico-Chirurgical Society; but the principle of the hazard being less in proportion as the operation is early, applies to every important surgical operation without exception. Every body knows, for instance, that though the operation for hernia may be performed with comparative safety while the constitution and the parts adjoining the seat of the disease are sound, yet no one would think of performing such an operation, comparatively safe though it may be, while there is much probability of removing the disease by less hazardous and milder measures*.

* If these, indeed, were only those at present generally in use, it might be a question whether the patient's interests would not be better consulted by at once liberating the intestine by the knife; but, as I have lately endeavoured to shew, in an essay on the subject, that the means in question may not only be much improved and extended, but the more efficient class of them may be used in combination, instead of the isolated manner in which they are at present employed. There is, in my opinion, as much defect in the preliminary measures adopted at present in strangulated hernia, as there would be in those preliminary to paracentesis for the removal of effusion from pleuritis, were bleeding, antimony, or mercury, totally laid aside, or employed successively instead of simultaneously. If the proper preliminary measures (as they are called) are adopted in hernia, the operation for it will, I am persuaded, be as rare as another capital operation, namely the

3. That the operation, although not without inherent danger, has been too much neglected; that it ought, in many cases, to be resorted to in preference to a reliance on the efforts of nature, or the remedial measures at present in use; and this, not only to avoid a fatal termination, but to render the cure more complete.

The points yet undecided are principally,—

1st, the proper mode of performing the operation, particularly as regards the exclusion of air; and, 2dly, the proper time or stage of the disease for performing it—whether it ought to be regarded as a valuable remedy in the earlier stage, or merely as a last resource.

1. It has been the fashion amongst English surgeons for some time past (an absurd fashion, introduced, I believe, by the late Mr. John Bell) to express, on all occasions, the greatest aversion to any thing like complexity in their apparatus. Mechanical science, so far as regards them, may be said to exist in vain; consequently the various expedients, more or less perfect, which have been used on the continent to prevent the entrance of air into the thorax, have never been adopted in England, as being inconsistent with the English love of simplicity. In the discussion on paracentesis already alluded to, at the Medico-Chirurgical Society, a distinguished member recommended, with a view to the exclusion of the air, that a steady pressure, by the hands of an assistant, should be kept up on the thorax until the extraction of the trocar; and that only a part of the effused fluid should be withdrawn. It is scarcely necessary to state that this is a most uncertain mode of attaining the object; and even were it otherwise, by retaining part of the pus, the object would be attained at too great cost.

Previously to describing what I think would be an improvement on the methods at present in use, it is necessary that I should state my opinion that the entrance of air into the cavity of the chest is not the sole cause of the ultimate aggravation of symptoms, and fatal re-

that of the trepan (once resorted to on almost every occasion of injury to the head), has now fortunately become. And it may be that paracentesis thoracis will likewise be rendered as unnecessary by a similar improvement in preliminary measures.

sults, that have so often followed the immediate though short relief obtained by paracentesis. In addition to this, I conceive that there is frequently irritation produced by the sudden and forcible distension of the lung and its investing false membranes, from the ingress of air through the trachea.

To obviate the entrance of air through the trocar into the cavity between the pleuræ, and the irritation from distension, I would propose keeping the outer end of the narrow trocar in distilled water while the effused liquid is escaping, in order that the water may be sucked into the pleural cavity in the event of the lungs not easily yielding to the air admitted by the trachea; and at the same time any entrance of air by the puncture in the skin may be prevented by surrounding the trocar, where it passes through it (the puncture having been made in the manner recommended by Dupuytren,) by some soft adhesive matter. It is long since the idea of placing the patient in a bath occurred to me, but there are many objections to such a plan, which, however, as we learn from Dr. C. J. B. Williams, has been lately successfully employed in Germany. The difficulty which first presents itself in the plan which I have proposed, of keeping the end of the trocar steadily at a small depth in the water, is surmounted by fixing it for the time to the bottom of a shallow vessel connected with another containing a large supply of water, on the principle of the bird-glass—as a teacup or saucer may be supplied with water from a quart bottle inverted in it.

The same purposes might perhaps be as well, if not better, attained by allowing the pus to escape through a trocar, round the outer end of which a bladder has been tied, containing some unirritating and in other respects innocuous gas. And still farther to guard against the sudden expansion of the lung, or stretching of its investing membranes, this gas (azote?) might perhaps be forced through the trocar at an early period of the operation, so as to occupy the whole or part of the space occupied by the fluid, until it should be removed by absorption. Useful facts in connection with this subject might be established by a very few experiments in comparative physiology.

2. Were the operation thus divested of the hazard usually attending it, and rendered as safe as the minor operation of opening a common abscess, it would be an easy matter to determine under what circumstances it should be performed. Whenever it was ascertained, by having recourse to the diagnostic means for which we are indebted to Laennec and Avenbrugger, that absorption was not taking place so rapidly as it usually does in cases where the cure is rendered complete by this alone, and where there is consequently danger of loss of function in the lung by its long-continued compression, then would be the proper period for the application of this remedy. If delayed until the lung has become bound down by false membrane, or been made itself incapable of expansion, the mischief will not only be to a certain degree irremediable, but it is questionable whether, under ordinary circumstances, much of the pus could then be removed, unless some such expedient as supplanting it by an innocuous gas were resorted to. And is not the want of expansibility in the lung in many cases of chronic pleuritis a principal cause of the effused fluid being so slowly removed by absorption? Where the lung is permanently compressed, the rising of the ribs (if still capable of motion) and depression of the diaphragm will cause a disposition to a vacuum in the cavity of the pleura. Does not the same disposition act injuriously in pneumonia, by producing vascular congestion where the expansibility of the lung is diminished by disease? Supposing that such a gas as has been indicated could be safely injected between the pleuræ in such quantity as to compress the lung and prevent its motion, in cases of pneumonia, hæmorrhage from, or ulceration of the lungs, where (as is generally the case) one side is only affected, and where it is desirable that the diseased part should remain undisturbed, what would be the effect? In order to reply to these questions there would be a necessity for referring to many yet undetermined points in physiology, and instituting an inquiry incompatible with the purpose of these practical observations. At some future time I shall resume the subject.

Brighton, July 1844.

COUNTERFEIT BLINDNESS;
INVOLVING A CAUTION TO SPECTATORS OF
MESMERIC EXHIBITIONS.

To the Editor of the Medical Gazette.

SIR,
WITHOUT at present agitating the question of mesmerism, or at least that part of it which regards clair-voyance, &c., it may not be mal-à-propos to remind the public, that deception may be carried to a very great extent—by well-organized collusion, to a point almost incredible. Of this the following extract from M'Crie's Life of John Knox affords one of the most remarkable examples.

I have the honour to be, sir,

Your obedient servant,

GEORGE LEFEVRE, M.D.

London, July 1844.

In the neighbourhood of Musselburgh was a chapel dedicated to our Lady of Loretto, the sanctity of which was increased from its having been the favourite abode of the celebrated Thomas the Hermit. To this sacred place the inhabitants of Scotland, from time immemorial, had repaired in pilgrimage, to present their offerings to the Virgin, and to experience the virtue of her prayers, and the healing power of the wonder-working "Hermit of Lareit."

In the course of the year 1559, public notice was given by the friars that they intended to put the truth of their religion to the proof, by performing a miracle at the Chapel of Loretto, upon a young man who had been born blind.

On the day appointed, a vast concourse of people assembled from the three Lothians. The young man, accompanied by a solemn procession of monks, was conducted to a scaffold erected on the outside of the chapel, and was exhibited to the multitude. Many of them knew him to be the blind man whom they had often seen begging, and whose necessities they had relieved. All looked upon him, and pronounced him, stone blind. The friars then proceeded to their devotions with great fervency, invoking the assistance of the Virgin at whose shrine they stood, and of all the saints whom they honoured; and after some time spent in prayers and religious ceremonies, the blind man *opened his eyes*, to

the astonishment of the spectators. Having returned thanks to the friars and their saintly patrons for this wonderful cure, he was allowed to go down from the scaffold to gratify the curiosity of the people, and to receive their alms.

It happened that there was among the crowd a gentleman of Fife, Robert Colville, of Cleish, who, from his romantic bravery, was usually called Squire Meldrum, in allusion to a person of that name who had been celebrated by Sir David Lindsay. He was of Protestant principles, but his wife was a Roman Catholic, and she being pregnant at the time, had sent a servant with a present to the Chapel of Loretto, to procure the assistance of the Virgin in her approaching labour. The squire was too gallant to hurt his lady's feelings by prohibiting the present from being sent off, but he resolved to prevent the superstitious offering; and with that view had come to Musselburgh. He had witnessed the miracle of curing the blind man with the distrust natural to a Protestant, and he determined if possible to detect the imposition before he left the place. Wherefore, having sought out the young man from the crowd, he put a piece of money of considerable value into his hand, and persuaded him to accompany him to his lodgings in Edinburgh. Taking him along with him into a private room, and locking the door, he told him plainly that he was convinced he had engaged in a wicked conspiracy with the friars to impose upon the credulity of the people, and at last drew from him the secret of the story. When a boy, he had been employed to tend the cattle belonging to the Nuns of Sciennes, in the vicinity of Edinburgh, and had attracted their attention by a peculiar faculty of turning up the whites of his eyes, and of keeping them in this position so as to appear quite blind. This being reported to some of the friars in the city, they immediately conceived the design of making him subservient to their purposes; and having prevailed on the Sisters of Sciennes to part with the poor boy, they lodged him in one of their cells. By daily practising he became an adept in the art of counterfeiting blindness; and after he had remained so long in concealment as not to be recognized by his

former acquaintances, he was sent forth to beg as a blind pauper, the friars having previously bound him by a solemn vow not to reveal the secret. To confirm his narrative, "he played his part before Cleish, by *flying* up the lids of his eyes, and casting up the whites, so as to appear as blind as he did on the scaffold at Loretto."—*M'Crie's Life of John Knox*, vol. i. p. 324.

MEDICAL GAZETTE.

Friday, August 2, 1844.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."
CICERO.

ANOTHER AND A LAST WORD ON MESMERISM.

WE had no conception that mesmerism was any thing half so silly as we find it to be in fact. The mysterious, the awful, the incomprehensible, have a certain influence over most minds; and, not understanding the principles of animal magnetism, we were really prepared for something that should appeal to our innate sense of the supernatural, when we went, on special invitation, as witness to an exhibition of Alexis the somnambulist. We were wofully disappointed, and from first to last saw nothing but the most flimsy attempts at trickery and imposition either successfully baffled, or as easily exposed. Alexis is neither more nor less than a poor juggler, and not to be compared with Herr Döbler, who is a gentleman, and can look his assembly in the face with a pleasant and an open expression of countenance; and why? Because he feels that he is an honest man, and wins his bread by innocently amusing us for an hour, by taking us out of our present selves for a brief interval, and restoring us to our childhood again. We have a respect for Herr Döbler, all the more, because we

have been given to wit that he is actually one of ourselves, or was intended to have been so at all events, had he not happily fallen in with a more lucrative profession. We love Herr Döbler, then; we respect him. We cannot say that we love Monsieur Alexis; the lad has an unhappy scowl; he looks out from the corners of his eyes, he is given to biting his nails, and has altogether the air of one addicted not to open, honest legerdemain, like Herr Döbler, but to downright deception. As to M. Marcillet, his magnetizer (!), who has been spoken of as Alexis's master, we very much doubt the correctness of this view. M. Marcillet, we are strongly inclined to believe, is sincere in his faith in mesmerism; and far from being the *master*, we strongly suspect that he is the *man*; the biter, in one sense, is himself well bitten. M. Alexis does not only *do* the gaping world of wonder-mongers; he *does* his bosom friend. *Mutatis mutandis*, M. Marcillet seems to us the 'Oliver Twist,' "so jolly green," rather than the 'Fagan' of the story: M. Alexis, 'the Artful Dodger,' not only robs his master, but he does it with such consummate skill, that his master never even suspects that he is robbed. It requires some one standing aloof and looking on, to see that all the articles do not come from the salt-box, and the pocket, where they have been purposely stowed, to exercise the ingenuity of the young aspirant to accommodation at the public charge.

But we have made up our mind about mesmerism: it all comes of the innate love of the marvellous, and the difficulty in the present overcrowded state of society of gaining an honest livelihood. Here is, in fact, a young man who would probably find it no easy matter to meet with opportunities to earn his daily bread by wide-awake-

work from sun-up to sun-down, who lives luxuriously, lies warm, and has white and soft hands, all by dint of appealing to the love of the wonderful in human nature! Had Alexis one faculty that was useful to mankind, he might run the risk of starving; did he live, it would be by dint of honest application in a tailor's or a grocer's, or a haberdasher's shop perchance; but the lad is absolutely useless; he can only go to sleep, or pretend to go to sleep, and in a dreamy state, with eyes half open, do nothing that had not as well be left undone; play tricks that are utterly stale, and make guesses that are not beyond the sagacity of a child five years of age; and forthwith he is an object of especial consideration! he is invited to the houses of noblemen and gentlemen, and is well paid for the impositions he practises upon them into the bargain, instead of being taken before the Magistrate as a rogue and vagabond, introduced to the Governor of the House of Correction, and by him presented to the proper functionary, to be shown the wheel that turns without advancing.

But idleness is said to be natural to man; to escape regular work, it is well known that there is many a lazy lout who will endure a good deal even of temporary bodily pain. Theodore Hooke hit off one of the secrets of these mesmeristic exhibitions admirably: "What on earth can have brought you to this line of life?" said one quondam friend to another, after having seen him publicly mesmerized and submit to have pins thrust through the gristle of his nose and the lobes of his ears,—"What on earth can have brought you to this pass?" "The necessity of living, my friend!" "And what may you have for your services?" "*Three-and-sixpence for the exhibition, and a shilling for each pin!*"

And M. Marcillet, too; who knows

aught of him, and how he lives, although he styles himself a *negociant* of Paris? he also may find it hard to live; and, a second Trinculo, may have said to himself: "Were I in England now, and had this fish painted, not a holiday fool but would give a piece of silver—there would this monster make a man: when they will not give a doit to relieve a lame beggar, they will lay out ten to see a dead Indian." And, in truth, though we hate imposition, and cannot help feeling contempt in our secret soul for all of easy faith who are the dupes of the vast variety of impostors and quacks—mesmerists, homœopathists, and hydropathists, professed squint-cutters and rectum doctors, curers of cancer and consumption, *et hoc genus omne*, who sail under the ensign of ignorance and dishonesty,—we feel no pity for the victims, and cannot help seeing that their depredators are, in a certain sense, *clever fellows*, men who can make silver spoons out of rams' horns, and silken purses out of asses' ears.

So often as mesmerism has been tested by competent persons, it has been exposed, and proved beyond a shadow of doubt to be delusion and deception. Alexis never succeeds save in presence of an assembly composed in large proportion of credulous women. He owned in our hearing, to the question put to him by a physician, that he always failed before "*les grandes personages de l'Académie*," such as M. Arago, M. Biot, &c. and he spoke of his successes at other times as *coups*—strokes, lucky hits. He fails when there is intellect and the habit of research to test him in rare instances; he succeeds in other and ordinary cases when he has incompetence and credulity as his judges and jury—*vulgus vult decipi, et decipitur*.

This calling in of the male sex as the pathic in mesmeric exhibitions, has done a good deal to open the eyes of

the reasonable public to the deceptions of the system; the most complete exposures have taken place with boys as the sleepers and clear-seers. With a youth we have no reserve; we try him home, and care not to make him blush, and prove him openly a cheat. We cannot do so with a woman. For our own part, we have always heartily pitied the poor young creature who is the ordinary victim of the arts of the mesmerist; it is but another kind of seduction on his part; another kind of prostitution on the part of the pathic; for what woman of mind and true delicacy would submit to have her senses sealed by a bearded fellow, in private, or to expose herself in the helpless state of sleep to the rude gaze of a crowd of men? We have instinctively seen the fact of women being the usual subjects of mesmerism, as evidence of the power of the strong over the weak: *mesmerism* is certainly sexual in a great measure; it is woman's nature to please her lord and master in any way. She may say with Viola, indeed—

"Alas! our frailty is the cause, not we;
For such as we are made of such we be."

We add a few lines more from our indigenous Bible of morals and philosophy, for the especial guidance and safeguard of our fair friends, and as a warning to them to beware of mesmerisers as among the number of those who would degrade them. Let them still say with Viola—

"Disguise, I see thou art a wickedness
Wherein the pregnant enemy does much.—
How easy is it for the proper false
In women's waxen heart to set their forms!"

And now, with an apology to our friends that we have ever occupied them with this subject of mesmerism at all, we promise to do so no more. To those who are not led away by their love of the marvellous, but who may be in doubt upon the matter, we close what we have to say upon it in these words of wisdom from the pen of one of the

most distinguished physiologists and able and candid inquirers the world has ever seen, Dr. Johannes Müller. Speaking of the so-called animal magnetism, he says :

“ These tales, however, are a lamentable tissue of falsehood, deception, and credulity ; and from them we have only learned how incapable most medical men are of instituting an experimental investigation, how little idea they have of a logical criticism, which in other natural sciences has become a universal method. There is no single fact relating to this doctrine which is free from doubt, *except the certainty of endless deceptions* ; and in the practice of medicine there is also no fact which can be connected with these wonders, except the often repeated, but still unconfirmed accounts of the cure of paralysis by investing the limbs with the bodies of animals just killed, and willingly credited fables of the restoration of youth to the old and diseased by their being in the proximity and exposed to the exhalation of healthy children.”

ELECTION OF THE NEW COUNCILLORS AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

ON Wednesday last, a meeting of the Fellows was held in the Theatre of the Royal College of Surgeons, for the purpose of electing three additional councillors under the provisions of the new Charter. There were about a hundred and twenty Fellows present ; among them we observed the majority of the members of the Council, and several provincial Fellows—Mr Cother of Gloucester, Mr. Soden of Bath, Mr. Wickham of Winchester, and others.

At three, the President (Sir Benjamin Brodie) took the chair, supported on either side by the vice-presidents, Mr. Samuel Cooper, and Mr. Lawrence : the secretary, and the solicitor of the College, were present.

The President said that the Fellows were assembled on the present occasion to elect three new members of Council, according to the provisions of the new charter. It would be impossible for him, considering the quantity of

business to be dispatched, to express what he felt, but this much he would say, that if any thing could increase the interest which he felt in the profession, it was presiding over so large and respectable assembly on the present occasion. It was desirable to have on the council not only men who had distinguished themselves in their profession, but men of business-like habits, who would not grudge the time in attending to the various concerns of the College, sometimes day after day, in committee ; for the museum, library, and general affairs of the institution, involved great care, and required much attention. The Secretary would now read over the section of the charter and bye-laws relative to the election, if any Fellow desired it, and then read twice over the names of each Fellow, and when any one wished to nominate a Fellow, he would state his intention, and fill up a form which he would find provided on the table. As a copy of the charter and bye-laws had been sent to each Fellow, the meeting might not, perhaps, require these to be read.

Mr. Cother observed that as this was the first meeting under the new charter, and considered offensive by a large body of the members, the proceedings could not be conducted with too strict an attention to formality. After some little discussion, the sections in the charter and bye-law, which we gave in our last number, relative to the election, were read by the Secretary. The names of the Fellows were then directed to be read over in chronological order.

Mr. Grainger begged, before the names were read, to ask the President whether it would be open to the Fellows to make any observations concerning the election or qualifications of candidates whom they might wish to nominate.

The President observed that, as in parliament no member could speak except by suffrage, unless he intended to end with a motion, so he thought, on the present occasion, the same rule should be observed. Still, if any Fellow had any observation to make, he would not wish this rule to be acted on too stringently, and would hear him. As to any observation on the merits of the candidate, he thought it highly inexpedient, and considered that these should not be discussed. Every one present is

supposed to have made himself acquainted with the claims of those who may be nominated, and observations in favour of any candidate might lead to replies, and remarks of an opposite character.

The Secretary then proceeded to read over the names of the Fellows, each name being read over twice in a slow and distinct manner.

On Sir Stephen Love Hammick's name being mentioned, Mr. Gay rose and begged to nominate him; the nomination was then signed by two other Fellows, and handed to the President.

The next name put in nomination, in the same form, was Mr. Montague Gossett.

On the name of Mr. Kingdon being called, a Fellow rose to nominate him, but Mr. K. declined the honour.

When Mr. Lloyd's name was read over, a Fellow immediately rose to nominate him; on which Mr. L. said that he had been urged by several friends to allow himself to be put in nomination, but as he had been treated by some of the Council most maliciously—he would repeat, most maliciously, as he was able to prove—he had come to the determination not to allow himself to be put in nomination.

Mr. Macilwain also declined to allow himself to be put in nomination, observing that, in the present constitution of the College, he could not possibly be of any service to the profession if elected.

Mr. Welbank was then nominated; and the number put in nomination being three, the ballot commenced, each Fellow, previous to balloting, signing his name and address in a book provided for the purpose. The balloting began at a quarter to four, and at twenty minutes past four all who intended voting seemed to have done so. At this time the President stated that, unless any Fellow ballotted within ten minutes, he should declare the ballot closed. At the expiration of the ten minutes, no Fellow having voted, the boxes were opened, and Mr. Welbank only was declared to be elected.

Mr. Scott and Mr. Cutler were then put in nomination, and, on the close of the ballot, declared to be elected. The names of the three new councillors, Mr. Welbank, Mr. Scott, and Mr. Cutler, were then formally announced.

The President said that he could not

allow the meeting to separate without thanking the Fellows for the regularity and care with which the proceedings had been conducted.

ON DRS. CRAWFORD & TWEEDIE'S VIEWS OF INFLAMMATION.

To the Editor of the Medical Gazette.

SIR,

SINCE Dr. Copland has taken no notice of the objections which have been brought against his views of the nature of inflammation, as contained in his Dictionary of Practical Medicine, it would seem as if he cared little whether the doctrines he teaches be right or wrong. It cannot be said that this is a point of no moment, however; for inasmuch as there is scarcely any disease in which the consideration of either a greater or less degree of inflammation is not sooner or later involved, truth and accuracy in such a question are of the very first and last importance. A correct interpretation of the phenomena of inflammation is, moreover, an *absolutely essential preliminary* to the right appreciation of the nature of fevers of all kinds; a question on which I shall have something to say hereafter.

I propose now to turn to the article on Inflammation, by Drs. Crawford and Tweedie, in the Cyclopædia of Practical Medicine. This work was ushered into the world with much circumstance and flourish; there was a long array of contributors, containing names already distinguished in the various departments of practical medicine; and I believe it was intimated that each article would be confided to the care of this or that individual, according as the subject matter of it might be connected with his previous and peculiar line of study, or accidental opportunities of observation. It is a work, therefore, of more pretension than Dr. Copland's Dictionary; and as the article on Inflammation has been considered of sufficient importance to be committed to the charge of more than one gentleman, we should expect to find the whole of the phenomena, both physiological and pathological, relating to it, developed with unusual clearness and precision. On this account I was much disappointed, in examining this article with the view of ascertaining what doctrines

are advocated by its authors, at finding what appeared to me a great want of decision, more particularly throughout the early part of it. It struck me very forcibly, and the impression grew stronger as I proceeded, that the writers evince more solicitude to avoid than to grapple with the difficulties of their subject; that they rather hope than believe the truth may be found between two wide extremes. Thus they say, for instance—"There has been much difference of opinion among physiologists respecting the degree of influence exercised by the brain and spinal marrow over the organs of circulation; some concluding from their experiments that the action of the heart and blood-vessels is wholly independent of this portion of the nervous system; while others adopt, as the result also of experiments, a directly opposite opinion. The *medium* between these contradictory views *approaches probably* the nearest to truth." In the next paragraph these gentlemen appear to adopt the first of these opinions, though it is only doubtfully expressed; and in the succeeding paragraph they give a quotation from Andral, which tends to support the last. Thus they touch gently on each side, as it were, with a trembling and a timid hand, disturbing every question and settling none, so that it is no easy matter to make out what are the precise opinions which they themselves entertain. At length, however, on entering upon the question of the irritability of arteries, the authors venture to speak so decisively, as to enable me to join issue with them: they say, "The facts brought forward, however, in support of the opinion that the extreme vessels possess a contractile power, appear to us so convincing and satisfactory, as to set aside completely the opposite theory." In this brief statement no argument is refuted, nor is any reference given as to where these facts may be met with: an attempt is made to cut through with a bold stroke what it was found inconvenient to unravel;—yet even here the writers' weakness and infirmity of purpose are no less manifest than in the example I have already mentioned; for in the very next paragraph they say, "Each theory appears to contain much that is true, especially that of Dr. Hastings;"

who is entirely opposed to the doctrine they had espoused. However, if these facts be so convincing, there can be no difficulty in producing or referring to them. For my own part, I can say that I have carefully gone into the details of probably some hundreds of experiments bearing upon this question; I have certainly not found the evidence which seems to have been so satisfactory to these gentlemen. I cannot but know that a general constriction of the extreme vessels, or perhaps, more correctly speaking, of the tissue which contains these vessels, by the application of certain agents, which constriction will *sometimes* be complete in *two minutes*, and which may *sometimes* be reproduced as many as *nine times* in an hour: but I never could understand that such facts as these contain any evidence of a capability of acting *many times in every minute*, and *many hundred times in every hour*. I should imagine, therefore, that some new facts which have escaped my observation must be alluded to; and I should feel obliged if either of the above mentioned gentlemen would have the goodness to point out where they may be found.—I have the honour to be, sir,

Your obedient servant,

J. W. EARLE.

Cheltenham, July 1844.

ST. GEORGE'S HOSPITAL.

TWO CASES OF FRACTURE OF THE SKULL; WITH OBSERVATIONS.

JOHN PICKLES, aged 45, on the 13th of April was riding on the top of a market-cart, when, having taken on his journey a considerable quantity of rum and water, he fell asleep: the cart in its progress came in contact with a lamp-post, and the concussion precipitated the man head foremost upon the pavement. He was immediately conveyed to St. George's Hospital in a state of insensibility: a considerable quantity of blood issued from the left ear, and a small quantity from the left nostril: the pupils were fixed, but not dilated: the limbs at first lay lifeless by his side; but he soon began to turn in bed. After he had been in the hospital for some time the pupils became dilated, and his mouth was at the same time observed to be drawn to the right side. He moaned in breathing, and the pulse was now 92, and rather sharp.

Sixteen ounces of blood were taken from the arm about a quarter of an hour after

his admission: the pulse at the same time rose in frequency, and became softer; the pupils regained their natural degree of contraction, and he became more quiet. Some time after the bleeding, the breathing became rather irregular; the pulse 88, soft, but intermittent, and the retraction of the mouth to the right side more evident. In the evening he regained his senses; but he passed a restless night. On the 14th, he answered very rationally the questions put to him, but with some abruptness of manner. The pulse remained at about 80; and he got some undisturbed sleep: pupils natural: could hear very indistinctly with the left ear, and said he supposed he had caught a cold in it.

On the 15th the pulse remained at 80, and the sharpness of manner had diminished.

17th.—Some peculiarity of manner remained, with slight pain in the head: no paralysis was now observable.

22d.—Had passed a restless night—head-ache.

29th.—Slight deafness on the left side was the only symptom which remained.

30th.—He left the hospital.

Matthew Burt, 53 years of age, was on the 22d of April struck upon the top of the head by a quoit pitched from a distance of 17 yards. He fell to the ground, and remained insensible for about three minutes, after which he gradually recovered, and returned home. He passed a restless night, complaining of severe aching pain at the back part of his head, and, according to his wife's account, it was occasionally with difficulty that he could be kept in bed. On the morning after the accident he was brought to St. George's Hospital: a wound existed at the upper part of the head, exposing a depressed portion of bone one inch and a half in length, and half an inch in breadth, situated immediately over the longitudinal sinus. This portion of bone presented a fracture through its centre, the edges of which were more depressed than the surrounding parts. At the time of his admission into the hospital he was perfectly conscious, and appeared to experience little inconvenience from the injury. He had no sickness, and the pupils were natural—pulse 60, labouring: the crown of a trephine was applied at one extremity of the depressed portion of bone; the diploe of the bone was found occupied by extravasated blood, and the internal table separated from the external, and broken into several pieces. Nearly the whole of the depressed portion was therefore removed: the dura mater was not injured. After the operation, the pulse was 64: towards evening it rose to 84, and continued labouring. He complained at the same time of intense pain in the head, and giddiness.

Some blood drawn from the arm became buffed and cupped.

On the 25th, had passed a good night, and appeared much more tranquil than on the previous evening.

The breathing was easy, and the pain in the head less: pulse 120, jerking: a small quantity of blood taken from the arm did not become buffed or cupped. He was ordered calomel and opium. There was no material change in the symptoms till four o'clock in the afternoon, when he was suddenly seized with convulsive twitches of the whole body. There was no pain about the head, but he complained much of the lower part of his back, and at the same time became so restless that it was with difficulty he was kept in bed. He continued for two hours in this state, after which he lost his voice, and became comatose.

On the 25th, he remained perfectly insensible, even when sharply pinched; the pulse very rapid: the breathing not accompanied by stertor. He died at 4 P.M.

Post-mortem examination.—Some effusion of blood was found beneath the scalp, at the right and back part of the head. A portion of the inner table of the skull still remained slightly depressed in the situation of the injury. The dura mater exposed by the removal of the bone was covered with coagula of blood and lymph. The sub-arachnoid cellular tissue of the upper part of the left hemisphere of the brain presented in its structure an extensive effusion of sero-purulent fluid; and the surface of the brain in the same situation presented two small patches of minutely injected vessels. The cells of the pia mater, at the posterior part of the left hemisphere, were occupied by a small quantity of blood. The ventricles of the brain were much distended by a clear transparent serum; and the lining membrane of the lateral ventricles was rough, and presented the appearance of having been dusted with very small white sand. The lungs were gorged with blood and frothy serum.

A tendency to cerebral disease, indicated by the condition of the pia mater lining the ventricles, may perhaps have had some influence in determining the fatal result in the last of the above mentioned cases. The circumstance, however, which was the principal cause of the very different progress and termination, and which produced such very dissimilar symptoms in the two instances, was, that in the first a process analogous to the adhesive inflammation supervened; in the second, the inflammation established was of the suppurative kind.

The results of the adhesive, as differing from other kinds of inflammation, are well described

by Mr. Bell, in his *Principles of Surgery*. "The adhesive inflammation," he says, "is not attended with fever, pain, redness, or swelling, unless in the most trivial degree." A gentle swelling, which indicates the fullness but strong and healthy action of the vessels, an adhering part must bear: this increased action of the vessels stands upon the same footing with the healthy action of a part in forming or supporting any part of the system." "Adhesion prevents inflammation: when parts adhere they enter into a healthy action; they are entire, and do not inflame."

The adhesive inflammation is most frequently produced when divided parts are brought into contact; but this condition does not appear absolutely necessary. A similar process may take place between the different divided parts on one side of a wound, although separated from the corresponding parts on the opposite side: the different textures involved in the lesion may become united to each other by lymph, which presents a barrier to the inflammatory action, and prevents it extending beyond the requisite limit. An instance is recorded in Mr. Guthrie's work on *Injuries of the Head*, in which a fracture of the base of the skull was accompanied by destruction of a portion of the brain. A cavity containing a transparent fluid was found in the situation of the injury, seven months after the occurrence of the accident. The parietes of the cavity were formed above by the substance of the brain, below by the dura mater lining the upper aspect of the petrous portion of the temporal bone. The two layers of the arachnoid had in this case united around the injury, and prevented the extension of the inflammation between them.

In the first of the above cases, supposing the existence of a fracture at the base of the skull as indicated by the symptoms, the very favourable progress of the case may be attributed to the parts around the injury having become united by adhesion, thus preventing any extension of the inflammation. In the second case, adhesive inflammation did not occur, and the inflammatory action extended itself for a considerable distance in the subarachnoid cellular tissue.

THE MILITARY STATISTICAL REPORTS.

To the Editor of the Medical Gazette,

SIR,

OBSERVING in your publication of the 12th July some remarks upon the medical branch of the army, in which the name of my friend Mr. Marshall has been mentioned, and being tolerably well acquainted with the circumstances to which you allude, I take

leave to put you in possession of the following facts.

According to your observations, it would appear that you understand Mr. Marshall had been promoted from the rank of Deputy Inspector-General to that of Inspector of Hospitals, and that he had been awarded five shillings additional half-pay, as a reward for the assistance he rendered in the compilation of the Statistical Reports of the Army. Now, if my surmise be correct, I take leave to observe that you have been misinformed. Mr. Marshall received no step of rank on that account; and he draws not a farthing of half-pay more than his rank and length of service entitle him to.

In 1830 Mr. Marshall was promoted to the rank of Deputy Inspector of Hospitals, having at that time served about eighteen years as Staff Surgeon. For this step of rank he was indebted to the direct influence of Sir Henry Hardinge. Having been forthwith reduced to half-pay, he remained unemployed, much against his will, for a number of years. Towards the end of October 1835, he was placed on full-pay, Colonel Tulloch and he having been named to prosecute an inquiry into the sickness and mortality among the troops in the West Indies. Mr. Marshall and Colonel Tulloch were not selected for this duty from any personal favour, but simply in consequence of their having previously been engaged in the compilation of military statistics,—the former having been many years engaged in that interesting study, and the latter having published two excellent papers on the subject in question.

During the year 1836, Mr. Marshall left London, and was placed on the half-pay of the rank he attained in 1830; and he has not since been employed on full pay. I am unable to state exactly the cause which induced Mr. Marshall to retire in 1836, but I believe I may assert, that it was not on account of infirm health. One thing is certain, he received little countenance or encouragement in the execution of a very arduous undertaking; he did not even receive any addition to his lodging-money, to meet the extra expenses incident to a residence in the metropolis. This is no doubt a very small matter, but it is one of the many little circumstances that might be adduced, which were calculated to show that statistical investigations were not then held in high estimation; indeed, they have not yet attained their due value in some quarters. Although on half-pay, Mr. Marshall continued to render his friend Colonel Tulloch all the assistance which it was in his power to bestow; and this assistance has been uniformly acknowledged in the successive reports which have been presented to both Houses of Parliament. But so low is

the value put upon gratuitous or voluntary services, that I am not aware he has on this account received even the empty thanks of either the medical or military departments.

This is, however, not all. Mr. Marshall has been indirectly accused of claiming, along with Colonel Tulloch, undue credit for having converted the elementary details in the medical department into statistical reports. The absurdity of this charge sufficiently refutes itself. But it may be asked, to whom does the merit of making some use of the materials in the medical department belong? Regimental surgeons have great merit in collecting returns, and drawing up reports, which, however, in a detached state, may be of comparatively little value. Elementary statistical materials may be accumulated into masses, and hoarded so long, that they may become totally useless. Money itself has no value unless it be put into circulation. Having, I hope, undeceived you, in regard to the alleged reward given to Mr. Marshall, I will, for the present, abstain from entering upon any collateral topic.—I am, sir,

Your obedient servant,
"TRUTH."

Portsmouth, July 1844.

[God help us! it seems we get even less than we had imagined.—Ed. Gaz.]

GREEK LEPROSY IN SARDINIA.

THE Sardinian government have lately been led to institute particular inquiries into the prevalence of this formidable disease in their dominions; the result of which is, that about 100 persons have been found labouring under the true leprosy. Dr. Trompeo, the reporter, states that the disease agrees, in its nature and characters, entirely with the Eastern leprosy. He is of opinion that it is contagious, and that it might be got rid of by entirely isolating the diseased.—*Giorn. delle Scienz. Med. di Torino*, Jan. 1844.

[We, for our own part, after much study of this subject, feel assured that Dr. Trompeo is wrong; that the true leprosy is not contagious, and that it would not be got rid of by isolating its unhappy victims. This idea of contagion under such circumstances is a remnant of ignorance and barbarism.—Ed. Gaz.]

SMALL-POX IN THE METROPOLIS.

WE are sorry to announce the extensive prevalence or small-pox at this time among us. REVACCINATE, REVACCINATE, say we.

NOTICE TO CORRESPONDENTS.

Our esteemed friend and correspondent, Mr. Earle, will see by this day's GAZETTE that we have recovered and published his

critical letter on Inflammation, which had gone astray for some short time.

BOOKS RECEIVED.

Quacks and Quackery. A Remonstrance against the Sanction given by the Government, the Press, and the Public, to the System of Imposture and Fraud practised on the Ignorant and Credulous in the Quackeries of the day; with Remarks on Homoeopathy, Hydropathy, Mesmerism, Mesmero-Phrenology, &c. By a Medical Practitioner.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Gentlemen admitted Members on Friday, July 26.—W. Monsoll.—J. G. Grylls.—J. J. Littlewood.—G. W. Lillies.—R. K. Pierce.—R. Millar.—J. Sole.—G. Williams.—H. C. Lucas.—H. Edmonds.

THE LONDON MEDICAL GAZETTE,

BEING A
WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

FRIDAY, AUGUST 9, 1844.

THE LEPROSY IN NEW BRUNSWICK.

[Our readers will recollect the interesting report on this formidable disease by Mr. Skene, which we had lately the satisfaction of laying before them through the favour of the Director-General of the Army Medical Department. The subject has excited a great deal of alarm in Quebec, Montreal, and other commercial cities and towns on the shores of the St. Lawrence and elsewhere. As usual, the new disease has been regarded as contagious, and measures of precaution and quarantine, the establishment of lazarettos or leper-houses, and all the miseries of isolation from the rest of mankind enforced in regard to the unhappy sufferers from the disease, have been threatened. Dr. Boyle, of St. John (New Brunswick), has taken what we feel satisfied is the right view of this case; he sees no reason to believe that the disease is infectious, and is opposed to all measures of quarantine in reference to the districts where it prevails, as well as to the establishment of lazarettos especially dedicated to the accommodation of those who are labouring under it. We heartily concur with Dr. Boyle in all he has said, and in the views he has taken, and feel it both a pleasure and a duty to give currency to his ably written and soundly reasoned paper.—Ed. Gaz.]

Brief Remarks on "THE REPORT" laid before the Government of New Brunswick by the Medical Commission appointed by the Lieutenant-Governor to investigate the nature, causes, &c. of a disease termed Leprosy, prevailing in certain French Settlements in that Province bordering on the Gulf of St. Lawrence. By ALEX. BOYLE, M.D.

A representation having been made to the Lieutenant-Governor of New Brunswick, that a disease of a highly malignant and loathsome nature, receiving the name of *Leprosy*, had been discovered among the inhabitants of certain French Settlements in the Counties of Gloucester and Northumberland, in that Province, a Commission, composed of four Medical Gentlemen and

the French Clergyman residing in that district, was appointed for the purpose of investigating its nature and causes, and suggesting such measures as might be judged necessary for its prevention.—The Commission entered on this inquiry in March last; the result is now before the public; and a sum of £1000 has been granted by the Provincial Legislature, to enable the Government to carry into effect the measures proposed.

As they have "unanimously recommended the erection of a Lazaretto, the removal of the sick, and their strict seclusion in that establishment," as means necessary to guard against the extension of this malady, which they consider as not only hereditary, but *contagious*, I have been induced to examine some of the more prominent facts which they have brought forward in support of this opinion; with the view of determining how far it is expedient, on this occasion, and on the grounds exhibited, to have recourse to measures involving extreme hardship on individuals, and not devoid of injury to society, and which ought never to be adopted under the sanction of causes which admit of doubt;—and with what probability of success those measures are calculated to accomplish the end proposed.

It may, in the first place, be observed, that much confusion has been introduced into medical writings, in consequence of doubts respecting the disease to which the name of *Leprosy* more properly belongs; arising, as is supposed, from the inaccuracies of the translations of the Greek and Arabian authors who treat of this subject, and who have sometimes described, under the same title, three different affections, very distinct in character, namely, the Hebrew *Leprosy*, a scaly disease; the Elephant, or Barbadoes leg; and the "Tubercular" disease, now under consideration. It is, however, at present unnecessary to enter farther upon this subject, as the disease in question must be viewed under the aspect presented to—by the cases given in the "Report," which it is classed under this last denomination; and, as observations of modern date have removed much of the perplexity by which was obscured, there is less difficulty

assigning to each its proper place in nosological nomenclature.

The facts collected, and which form the subject of the official document, are interesting; and the cases are detailed with a degree of accuracy and clearness, leaving no doubt as to the existence of a disease which has all the characteristic symptoms of the "Tubercular Elephantiasis" of modern nosologists, the "Juzam" of the Arabians, and the "Lepra Græcorum" of the middle ages, by which its identity is fully established, and which, therefore, need not now be repeated.

It is stated in the "Report," that "no positive conclusion could be drawn as to its original appearance in this quarter;" but, that, according to the information that was received from the oldest settlers, the first case occurred in the person of Ursule Laudre, about the year 1817, nineteen years after her marriage with Joseph Benoit, of Tracadie, a small French settlement situated in a part of this Province, bordering on the Gulph of Saint Lawrence, and where she went to reside after her marriage. Her father, mother, and their children, *nineteen* in number, appear, with the exception of Ursule alone, to have been perfectly healthy. She was married about the year 1798 or 1799, and having been affected ten years *before* her husband, (for, it appears, he also became affected with it,) it would be absurd to suppose that she possibly could have received the infection from *him*; neither can we suppose that he could have contracted it from her, for he continued free from it until three years before her death, which happened in 1829; a period of twenty-six years after their marriage, and of his having lived with her about ten years *after* she had shewn all its unequivocal symptoms. After the birth of her fifth child, Ursule ceased to bear children; and it is stated that, from that time, her health continued to decline for six or eight years, when the disease was no longer doubtful.

Upon the whole, other facts stated in the "Report" are not more favourable to the existence of *contagion* as a cause of this disease, than those already mentioned; for, it is not shewn from whom Ursule received the infection, nor is it proved that she communicated the disease to any one, either by direct contact or through the medium of substances imbued with a contagious principle. There is, indeed, no sort of analogy, as far as those facts go, between this disease and those of a contagious nature; in most of which, we can, almost, as it were, detect the contagion in its passage; and it is only by analogy we can reason on the subject. The latent period in contagious diseases is never long—being only two or three days, sometimes less, and seldom exceeding three weeks; whereas, in the present instance, *several years* of continued intercourse inter-

vened from the first communication with the infected person to the time of its appearance in the individuals exposed.

As it is admitted by all that "Tubercular Elephantiasis," or the Greek Leprosy, as it is sometimes called, is an *hereditary* disease, and, like Scrofula, may pass one generation and appear in the next, when concurring causes favour its development, the tint is one of the nineteen children of Landreville (Ursule) may have been derived from a source to which, at this distance of time, it cannot perhaps be traced; and the case of the only one of her five children who was affected must be referred to the same category; while the exemption of the other four, though living in continual intercourse, completely overturns the doctrine of *contagion*, and is in perfect analogy with the facts observed in scrofula and other diseases which are transmitted from parents to their posterity, affecting some and sparing others, according to circumstances not often very evident or easily explained. The case of Frances Savoy is not less decisive. She has a family of six children, and only one, a boy of eight years of age, is affected. She herself has had the disease four years and a half, in a severe form; "her husband sleeps with her every night, and is in perfect health." P. Savoy's case is a severe one. He has a wife and four children, but all of them are apparently healthy. The case of T. Robichau bears equally on the same point. He is about fifteen years of age, and has been affected six years; and his uncle was recently carried off by it; marking, *decidedly*, *hereditary* transmission in that family.

It must, indeed, attract particular notice, as a singular feature in the "Report," that, as regards *contagion*, so many of the facts related militate strongly against the conclusion which has been deduced from them on this important question.

The affected district is situated between the Bay of Chaleur and Miramichi River, and the intercourse between it and Canada, Prince Edward Island, Nova Scotia, and the adjoining counties of New Brunswick, has been frequent and uninterrupted; and though the disease was known to have occasionally existed in some parts along the Gulf shore at a date anterior to that assigned to it in the "Report," it had not, it would appear, been propagated to any of the above-named places, nor been considered of that importance, or so frequent at the time, as to attract particular notice, or excite any serious alarm; and it is only now, though twelve cases terminated fatally, and, as appears by the "Report," after it had prevailed in Tracadie for a period of twenty-seven years, that the attention of the legislature has been called to it as fraught with public danger, and requiring rigid measures of prevention.

That the original source of the disease is

to be detected in any geological peculiarity observable in the tract of country above mentioned, is not very probable; atmospheric causes are temporary, though general in their operation, giving to diseases an epidemic character; and the climate and cultivation of the soil, if not much improved, certainly are not deteriorated. The habits and mode of living of the French inhabitants in that part of the Province of New Brunswick, it may also be remarked, have always been pretty much the same since its first settlement with those in other parts of British North America, except that the fish which constitutes almost their sole article of food is not, perhaps, of the same wholesome quality as among some of their neighbours, owing to their poverty, which often prevents them from procuring the means necessary to preserve it for use. Some further facts, therefore, are wanting, to render our conclusions as to the primary cause of its appearance in that locality satisfactory; and it is to be regretted that it could not now be traced farther back than the case of Ursule Landre, in 1817.

The inhabitants of this district are of the Norman race, and descended from those Frenchmen who visited North America at a very early period of its settlement; and by whom, it can scarcely be doubted, the disease was brought to this part of the world; and the superb structure erected by Henry II. Duke of Normandy, at Caen, in 1160, for the reception of lepers, (but long since appropriated to another use,) attests to this day the prevalence of the disease, in former times, in that country, where it had been, in a manner, naturalised since the time of the Crusades. It is of no small importance, therefore, as tending to throw a ray of light on this part of the inquiry, to know that Ursule's father was an "Acadian," that her mother was of "Caraquette," in the Bay of Chaleur, and her husband from "Tracadie," on the Gulf Shore: for it is also known that the *Baie de Chaleur* and the north-east shores of *Acadie* were places where those adventurous navigators first encountered perils; and the disease may have even disappeared for a season, and at different periods from that early date sprung up again among their posterity, who appear still to inherit the original taint.

From the facts stated, it does not appear what has been the total number of cases from the year 1817, until the present time, although nineteen "confirmed" cases were found at the time of their visit; a proportion not exceeding, perhaps, that of any other disease, acute or chronic, which has appeared in this district during an equal period, reckoning from the average duration of the cases recorded in the Report; and it might, perhaps, be also ascertained that the deaths from any one of them were not less

numerous than those from leprosy, which, as far as we are informed, amount to twelve.

Having thus taken a brief review of the principal data furnished by the Report, and on which the Commissioners found their opinion as to the *contagious* character of the disease, which alone could warrant recourse to the seclusion of the affected, and the adoption of Lazaretto regulations and restrictions, it may not be deemed unprofitable or uninteresting, in a question which so deeply involves the comfort and safety of a large portion of society, to quote some *modern* authorities of the highest weight in the medical profession, in support of the opposite doctrine or *non contagious* nature of this loathsome disease, which is universally acknowledged to be *incurable*.

In an article in the "Dictionnaire de Médecine et Chirurgie Pratiques," by Bouillaud, vol. 5, p. 425, he says, "La contagion a été admise par certains auteurs dans une foule des cas où elle n'existe réellement pas. Quel est le médecin observateur qui ajoute foi maintenant à tout ce qui a été débité, par exemple, sur la contagion de la Lèpre, &c." And again, vol. 5, p. 435, when speaking of isolating the sick and of sanitary cordons, he expresses himself thus: "Les attaques dont cette mesure sanitaire a été l'objet dans ces derniers temps paraissent bien fondées, et le moment n'est peut-être pas éloigné où elle sera complètement abandonnée." To this effect, also, in an article in the same work, vol. 14, p. 19, by Ch. Londe, when speaking of the instructions relating to Quarantine, he says, "La Lèpre arrive, dans les Instructions, en quatrième ligne; mais parmi les gens qui ont bien observé cette maladie, aucun aujourd'hui ne croit plus à sa propriété contagieuse; les dispositions atroces prises contre les lépreux sont tombées en désuétude, et ces malades sont admis parmi les autres dans nos hôpitaux, sans que jamais on se soit aperçu de la transmission de leur affection."

In a paper in the *Cyclopædia of Practical Medicine*, on "Contagion," by Dr. Joseph Brown, we find the following remark:—"There are two other diseases which were formerly considered contagious, *Leprosæ Græcorum* and *Leprosæ Arabum* (*Elephantiasis*). The former is unquestionably not contagious; and from the observations made by the late Dr. Adams in the Lazaar house at Funchal, there is every reason to think the latter equally devoid of that quality."

Numerous authorities* might be quoted to the same purpose, but the above are conclusive; and the proofs of *hereditary* transmission are not less clear and cogent.

Various external causes have been mentioned as producing this disease; and there

*Rayer, Bateman, Alibert, Robinson, T. Herbert, Ainsley,

is a general assent as to the agency of bad food, especially putrid fish, and vicinity to the sea shore. There is, however, in many instances, the greatest difficulty and uncertainty in accounting for its appearance; and the above, like those of a moral nature, of which a remarkable instance is recorded by the celebrated Alibert as coming under his own immediate care, (*Precis, &c.* vol. 2, p. 84), it is presumed, act chiefly by awakening a latent hereditary predisposition, and it must be confessed some cases baffle all conjecture. The testimony of Sonini and Pallas is referred to by the same author as opposed to the doctrine of *contagion*.

Having myself seen, some years ago, a well-marked case of this disease, which leads to conclusions in perfect accordance with the opinions of those eminent men, I may be permitted, in this place, to bring it under notice. It occurred in a person about thirty years of age, a native of Antigua. He had laboured under it for a considerable length of time, and came to Nova Scotia for the benefit of his health, where he married an interesting young lady, about two years before I saw him. After this he came to St. John, and was under the care of Dr. Boyd and myself for about two months. His breath was extremely offensive, and his hands, face, and legs were covered with blotches and tubercles of a livid, brownish colour; and some of them were in a state of ulceration. He afterwards went to New Orleans, in a worse state than when he first left the West Indies; and died of this disease not long after his arrival. During the whole period of his illness, from the time of his marriage, his wife was most assiduous in her attentions to him, and occupied the same bed; but neither she nor any of the inmates of the boarding-house, where they lodged for nearly twelve months, and with whom they had daily intercourse, ever shewed the least mark of the disease. He had no children; and after his death his wife returned to Nova Scotia, where she has continued to enjoy perfect health.

In the course of the above remarks I have purposely abstained from all opinions respecting the operation of contagious miasmata, or the manner of their introduction into the blood, as foreign to the object of the present inquiry; and as chemistry has hitherto thrown but feeble light on the nature of their elementary constituents, or the changes they effect on the circulating fluids.

Several important organs undergo a morbid alteration of structure during the progress of this disease; but as its pathology is unconnected with the question at issue, it need not now engage our attention.

It is generally admitted that pulmonary consumption is, according to the common acceptance of the term, an hereditary disease, usually developed by the action of

exciting causes. In some countries it is also deemed contagious; and the houses which have been occupied by persons who die of this complaint are always left deserted. In New Brunswick its occurrence is very frequent; and, though not deemed contagious, it may certainly be pronounced incurable. So far, the parallel between it and leprosy is strictly correct; but surely it would not be recommended that those persons labouring under pulmonary consumption throughout the province should be torn from their families and left to die in a *lazaretto*; nor can it be imagined that any such measure would be proposed to prevent the continuance of so great a scourge of the human race; as it is sufficiently evident how fruitless the attempt must be, by the removal of a few, to arrest the progress of a disease whose germ, unhappily, is but too widely spread among mankind, and whose extinction is beyond the reach of legislative power.

During the prevalence of the Asiatic cholera in Europe, erroneous opinions regarding its contagious character led to the adoption of similar measures of prevention; but experience has since taught us how useless and unnecessary they were, and how injurious to the interests of society; and the novelty of the disease among us, and its still inexplicable nature, afford the only vindication of the course pursued during that period of general consternation. In no part of Europe was leprosy so prevalent at one time as in France, from the eleventh to sixteenth century. It is now chiefly confined to the tropical and equatorial regions, being rarely met with in Europe since the seventeenth century; and the advanced and more refined state of society accounts for its gradual disappearance; while greater experience has banished all dread of its supposed contagion, and opened their noble hospitals to the admission of lepers, without distinction, among other patients; and numerous lazarettos of great extent have long been converted into retreats for the aged and infirm, or like purposes of general philanthropy and benevolence.

I trust it will appear, from what I have said, and the authorities I have referred to, that any measures of prevention which require seclusion of the sick, much less the severity of Lazaretto regulations, are not warranted, on this occasion, by the facts on which their adoption is grounded; and as their uselessness and impolicy have nearly expunged them from the code of civilized nations.

The formation of any hospital *exclusively* for the reception of leprosy patients is also objectionable, as entailing an endless expense on the Province; especially if County Hospitals already exist, or similar establishments, into which, as experience has abundantly shewn, they may be received

without the "remotest injury to other patients; and of which the "Report" itself furnishes ample proof. The disease being incurable, little good is to be expected from hospital treatment; which, at best, could only be palliative. Much, however, may be done to obviate some of the causes which render the human body liable to various diseases arising from noxious emanations, as well as from atmospheric influence and hereditary predisposition, by inculcating the necessity of a proper hygiene throughout the French population of that district; by which the constitution may be enabled to resist the influence of external agents; and without which, it is to be feared, the disease will finally cease only with the extinction of the race.

With this view, inquiry should be made by the clergymen of the district to which the disease is confined, into the habits and means of subsistence of the several families under their pastoral care,—their occupations, their clothing, their ordinary food, and the state of their habitations; and according to their age, sex, and number of children, such pecuniary aid should be given as would relieve their wants, stimulate their industry, and, not less important, dispel despondency and grief, by shewing them that a general interest had been awakened in their favour, and that the present evil was not altogether beyond the reach of relief. The appropriations of money from the public purse for this humane and benevolent purpose should, for obvious reasons, be entrusted to the hands of the Roman Catholic Bishop of New Brunswick and the Pastors of the district; to be distributed at their discretion and responsibility, rendering an account of the disbursements to the Executive Government of the Province, which alone should have power to control them.

OBSERVATIONS ON FRACTURE OF THE PELVIS;

WITH A CASE.

By W. LYON, Esq.

Lecturer on Surgery, and lately one of the Surgeons of the Glasgow Royal Infirmary.

(For the London Medical Gazette.)

Fracture of the pelvis; laceration of the bladder; extravasation of urine; death. General observations on fractures of the pelvis.

FRANCIS SMITH, aged 14 years, carter, admitted into the Glasgow Royal Infirmary at 2 P.M. of Dec. 28th, 1843. About an hour and half ago, while the patient was in charge of a horse and

cart, the horse took fright, and suddenly darted forward, when the patient, in attempting to restrain him, was forcibly pressed between the cart-wheel and a large stone. He now complains of very acute pain over the whole of the abdomen, stretching down to the perineum, which is much swollen and ecchymosed. The right leg is abducted, and the toe everted. No motion or crepitation can be elicited in the bones of the pelvis by gently pressing them laterally, or in the anterior and posterior directions, or by alternately pushing up the one and drawing down the other limb. Skin cold; pulse scarcely perceptible.

A catheter to be introduced; warmth to be applied to the surface, and small quantities of some stimulant to be given from time to time; warm drinks, spirits and water, &c.

29th.—Has not rallied from the state of collapse, though he has had half an ounce of whisky every hour. To-day he has had constant vomiting, and increased pain in the abdomen and perineum; the perineum is more swollen than it was yesterday. Pulse 120, and with difficulty to be felt. The introduction of the catheter was not attempted last night, as ordered: it was tried this morning, and failed: the attempt was repeated to-day, but without success. A free incision was therefore made into the right side of the perineum, when a large quantity of bloody urine escaped.

To have turpentine fomentations to the abdomen, and an ounce of whisky every hour.

On the 30th the pulse had fallen to 96, but was still exceedingly feeble. The abdominal tenderness continued; urine was freely discharged from the wound; thirst urgent, and vomiting incessant.

He was ordered an enema; a grain of calomel every second hour; Prussic acid mixture; and a continuance of the fomentations.

Next day the pulse had become firm, and the skin warm; the vomiting had ceased. The abdominal tenderness was undiminished, and the bowels were unmoved, although the patient had taken an ounce of castor oil.

The oil to be repeated; the calomel to be used every hour. A blister over the abdomen. The whisky to be omitted.

The reaction was maintained for two days; six leeches were applied; the tenderness diminished, and the bowels were moved. The abdomen then became tympanitic; the pulse and strength gave way; and the patient died on the morning of Jan. 3d, about five days after receiving the injury.

Inspection.—Much ecchymosis on mesentery, mesocolon, mesorectum, &c., and also under the pelvic fascia. Peritoneal coat of intestines in some parts injected; soft parts of perineum completely disorganized, and a small opening existed on the right side of the bladder, a little behind its neck. The pelvis was found to have suffered great injury; the right acetabulum was much broken up, and the os innominatum separated from the ischium at the line of junction in the acetabulum, to such an extent that the head of the femur could be felt from the inside of the pelvis; so that I rather think the acetabulum must have communicated with the cavity of the peritoneum. The ossa pubis of right and left sides were fractured in their horizontal rami, immediately anterior to their parts of connection with the innominata. On the left side the fracture was comminuted, and several of the pointed fragments were directed internally. On the right side, the sharp extremity of one of the fractured pieces projected forwards and inwards, and had entered the antero-lateral aspect of the bladder, making an opening into that sac about the size of a common bean. The ischium of each side was fractured at two places, one of them being in the ramus, just above the tuberosity, and the other where the rami of the ischium and pubis unite. A fracture also extended from the upper to the lower part of the sacrum, on the right side, in a line through the foramina which transmit the sacral nerves.

The fractured portions were all considerably displaced, the lateral diameter of the pelvis diminished, and the pubes thrown forwards, causing a close resemblance to the form of antero-posterior pelvic distortion; and produced in this case by the pelvis being compressed laterally by the pressure of the cart-wheel on the trochanter of the one side, against that of the other, resisted by the stone, the pressure extending through the trochanter, by the heads of the femora in the acetabula.

This case afforded an illustration of

one of the most usual causes, and of the ordinary symptoms and consequences, of a severe pelvic fracture: the violence which produced it was extremely great, the diagnosis obscure, and the result fatal. Portions of the crest and ala of the ileum may be broken, without the consequences being important, although they sometimes are: of such injuries I have seen several cases; but their detail would neither interest nor instruct. The parts mentioned are so prominent, that comparatively slight forces may fracture them. Not so with the body of the pelvis, which, from its circular form, resists all but very powerful pressure; and the same force which fractures it is often sufficient at the same time to lacerate some one of the numerous and important organs which it contains, or to wound them by driving in the fractured portions, which are frequently pointed and sharp.

The blood-vessels*, the nerves, the peritoneal cavity, the bladder, the rectum, have severally, in cases of this kind, been found lacerated or punctured. In the case forming the subject of this paper the bladder only was wounded; but some of the blood-vessels narrowly escaped; the horizontal rami of both pubes being broken into numerous fragments, the sharp spicules of these were thrown up directly under the external iliac arteries and veins, in their passage from the pelvis into the groins.

Considering the thorough breaking up of the pelvis in the case narrated, it may excite surprise that mobility and crepitation of the fragments were not observed. One reason for this was, that such force was studiously avoided as would have been requisite to occasion crepitation, or to produce sufficient extent of displacement to have made unnatural motion evident; for the attempt, in fracture of the pelvis, to make the usual signs of fracture unequivocal, may either cause, or increase laceration of, or may push, or farther insert the extremities of the fragments into the peritoneal sac, urinary bladder, rectum, or blood-vessels, and therefore more than very gentle careful examination is replete with danger.

There was another reason for the obscurity in this case, which is common to a large proportion of similar injuries,

* Mr. Earle, *Med.-Chirurg. Transactions*, vol. xix. p. 263.

and which points out the mode of examination which should be practised for their detection. The fracture that ran through the sacrum was not complete; that is, there was not separation of the fractured surfaces, so as to give capability for much motion; the bone had been only bent or verged over, so that, although the circle of the pelvis was destroyed in front, the two posterior thirds partially retained their normal form, and either did not move at all, or only very slightly, by the pressure which was applied alternately to the ilia by the hands placed on the spinous processes, and to the acetabula, by raising or depressing the limbs. Again, owing to the depth of the fragments from the surface, and possibly also from the blood extravasated between their surfaces, the fractures of the pubes and ischia were not recognised by pressing over the brim of the pelvis anteriorly. These particulars are of importance as shewing that the absence of motion sufficient to be noticed, and to make crepitation observable, is not incompatible with the existence of serious and extensive fracture, and that therefore in suspicious cases we should not only seek information by gentle attempts to rub the fractured surfaces together, by alternate pressure of the fingers upwards and downwards round the entire upper and lower lines of the pelvis— attempts at elevation, depression, and anterior and posterior motion of the ilia—but should try to obtain further information by inserting the finger into one of the outlets of the pelvis, and carefully exploring all parts within its reach: had such been done in this case, I have no doubt but some of the fractures would have been discovered.

The *abduction* of the right leg, and the *eversion* of the toe, consequent on the change of relation of parts within the broken-up acetabulum, were not in this case likely to mislead by inducing a belief of fracture of the neck of the femur, the more especially as crepitation was not observable: and the normal, or nearly normal length of the limb, though it was abducted, dissipated all suspicion of dislocation into the foramen ovale, a case where, of course, the limb is in addition longer than its fellow.

Where the separation of the fragments has been greater than in this instance, permitting the head of the femur to sink inwards, and rub on the

fractured surfaces, the diagnosis has been somewhat obscured. In such circumstances the existence of crepitation, the eversion of the toe, the shortening of the limb, the diminished arc in which the rotated trochanter would appear to move, its altered position, and change as to performance, are all symptoms common to fracture of the neck of the femur; but in the latter injury the specified conditions exist in greater degree, especially so the shortening, while in breaking up of the acetabulum, the trochanter, in place of being more, as in fracture of the neck of the femur, is less than normally prominent*: the mode of reception, and the presence or absence of considerable shock, will aid the diagnosis. I have a preparation in which about a third part of the superior portion of the acetabulum is broken off and detached, permitting the head of the femur to slip up and occupy the place of the fragment. Of this preparation I have not any history, but from there being partial dislocation combined with fracture, there must have been a mixing up of symptoms which would have made a correct diagnosis very difficult to be arrived at.

A somewhat similar state of parts, but allowing complete dislocation, must have existed in a patient I had some years ago with dislocation on the dorsum ilii: the dislocation was easily reduced, but as the man had no proper home he was after the reduction carried to the hospital, where the attending surgeon satisfied himself that all was right. After a few days the patient rose to walk, and felt something give way in the injured joint, which became painful. On now measuring the length of the limbs, the injured one was found shortened, and remained so, and no doubt the shortening was occasioned by a portion of the superior part of the acetabulum having been detached when the femur was dislocated; this was replaced at the time of the reduction, and again slipped upwards when the weight of the body was thrown on it by the head of the femur in walking.

These cases are not in strict connection with breaking up of the acetabulum, where the head of the femur sinks more or less inwards between the fragments, and thus, as already described, is apt to be confounded with

* Mr. Earle, *Med. Chir. Trans.* vol. iii. p. 251-2.

fracture of the neck of the femur; and I have only introduced them here for the purpose of drawing attention to the difficulties in diagnosis which may arise from the complicated injuries to which the parts composing the hip-joint are liable.

Though the existence of fracture was not rendered evident by examination in the case giving rise to the present remarks, the mode in which the injury was received, combined with the intensity of the symptoms, made the nature of the injury strongly suspected; and therefore, to prevent the dangers which are common in fracture of the pelvis from penetration of the bladder by fragments, and consequent extravasation of urine, the insertion and retention of a catheter were ordered. The introduction of a catheter was neglected until it could not be accomplished; and though it had been passed, it was too late to obtain all the advantages that belong to the practice when instituted early: it was delayed until the extravasation of urine had broken up the tissues in the pelvis and perineum, occasioning all its serious local and constitutional injurious effects; displacing the urethra so that the ordinary direction of the canal could not be followed, and necessitating the only remaining resource, the free incision into the perineum, from which immediate relief was experienced.

The wound in the bladder was here below the point of reflexion of the peritoneum, and therefore the urine was prevented passing into the pelvic cavity, and made its way through the wound in the pelvic fascia and levator ani to the perineum. Even here the risks were greatly increased by the extravasation; where the wound of the bladder opens into the peritoneal sac, the passage of urine into it is certain to occasion death. And as in severe injuries of the pelvis, although positive proof of fracture be wanting, we cannot be sure that the bladder may not have suffered, the catheter should always be used as a preventive of extravasation of urine, not as a remedy for it.

The deep depression caused by the extent and severity of the lesions, and the blood extravasated into the folds of the peritoneum, necessitated the use of stimulants, which, however, were interrupted the moment reaction occurred. Calomel was likewise exhibited, on the supposition that the intense pain

in the abdomen indicated peritonitis; but the absence of effusion and adhesion renders that conclusion doubtful. Had the patient been carried over the period of shock, we have proofs, from histories of somewhat similar instances, and from somewhat analogous circumstances in fractures of the cranium and ribs, where the danger arises secondarily from implication of the contained organs, that inflammation, and possibly suppuration, would still very probably have destroyed him. Indeed, we can scarcely conceive that recovery could have been effected where there were combined extensive fracture entering both hip-joints, running in immediate contact with the sacral nerves, in close connection, probably communicating, with the excitable peritoneum, the bladder punctured, and, nearly as bad as any of these, but which might have been prevented, the depressing and destructive influence of extensive urinous infiltration*.

With a view to prevent motion of the fragments, almost all authorities recommend the fractured pelvis to be surrounded and compressed by a belt or bandage. Now, upon examining the pelvis, which I possess, of the patient whose case forms the subject of this paper, and reflecting on fractures of the pelvis generally, I cannot avoid thinking that the practice of applying compression is generally highly improper. We can imagine a case in which, from the surfaces of the fractured bone being perfectly transverse, compression would hold the portions together. We can seldom, however, recognise such a particular state with certainty, and where there is any obliquity of the fractured surfaces, or there is fracture at more than one point, so as to permit motion of the portions, it is evident that compression by a bandage must have all the prejudicial tendencies of pressure during examination, a practice already reprobated; that must throw in the extremities of the fragments, generally sharp, and often, as in our case, pointed; bandaging, therefore, should, in our opinion, rarely — we had almost said never — be employed.

There are, however, two conditions which, if present, might justify the trial of a bandage round the pelvis — the absence of any discoverable dis-

* See cases of recovery from very severe, but not equally severe injuries as this, by Mr. Earle, in Vol. III. of *Medico-Chirurgical Transactions*, p. 249.

placement, and a feeling of comfort, a relief from pain, when the pelvis was compressed or supported: the one of these it is difficult, if not impracticable, to ascertain, and in using pressure to determine the other, we may cause the very danger we seek to avoid.

It would be a practice more in consonance with reason and observation to use measures of an entirely opposite description; to attempt to expand the often narrowed pelvis, and to extricate the extremities of the driven in fragments from the important contained tissues and organs, by making moderate pressure upon the anterior superior spinous processes in a direction outwards and backwards; or to produce a similar effect by gentle extension in opposite directions from the highest points practicable of the heads of the femora. On a similar principle, if a case were presenting where there was reason to believe that there was fracture of the pelvis into two or more portions, which were driven in, and passing each other, by placing a pillow between the thighs close to the perineum, and retaining the limbs extended and bandaged firmly together, so that the pillow should serve as a fulcrum on which the thighs acted as levers, the fragments might probably be thrown and kept out in their proper positions.

It is possible to conceive fragments of such form, and so situated, that the method above recommended would cause them to produce laceration or puncture, or to increase such injuries if they existed; or that it would separate fragments further, or throw in spiculæ tearing or puncturing the soft parts inside of the pelvis*; but such cases must be rare, and the practice, if carried out with any regard to caution, is at least safe, when compared to the opposite method of forcing the fragments further in by compressing with the hands or a bandage round the pelvis. But of course the pelvis may be fractured at any point, and there must be many instances where the ilia, though fractured, are not displaced; many where the ischia or pubes are fractured and displaced, the ilia remaining intact; and in each of these supposed cases no advantage would be gained by acting on the ilea as I have recom-

mended. If, however, it be kept in view that in fractures of the pelvis, if there be displacement, the fragments are almost always driven *inwards*, and are frequently loose, it will be apparent that the usual practice of surrounding the pelvis with a bandage is irrational and dangerous, and should yield to the generally, though not universally, beneficial principle of using means to throw out, and keep the broken portions of the pelvis expanded.

Supposing a fragment to have entered the bladder, the likelihood of which will be a good deal influenced by the full or empty state of the viscus at the time of the accident, or to be so displaced as to puncture the urethra, on the former supposition, the bladder, when it contracts, will in all probability withdraw itself from the fragment, and the urine escape by the urethra, or from an incision; if the case otherwise proceeds favourably, the wound in the bladder will soon heal, and the urine escape by the natural channel.

In the latter circumstance, that is, where a fragment punctures, or presses on, the urethra, by making attempts to carry out the fragments, and expand the pelvis; or, on the same principle, by pressure directed upon them within the pelvis, through the parietes of the vagina, or rectum, as the case may be; the passage of the retained urine through the urethra, or from an incision, or by the introduction of the catheter, will be almost always practicable, and will supersede the difficult, painful, and by conversion of a simple into a compound fracture, the dangerous recommendation of the justly celebrated Boyer, in whose work, which even now is probably the most able, comprehensive, and yet minute treatise we possess on fractures, we are advised, in the conditions above stated, "to cut down upon and extract the fragments*."

The conversion of a complicated fracture into a compound one, we do indeed generally cause, when we incise on account of extravasation of urine in

* See particulars of a case where my proposal (if injudiciously employed) might have been injurious. Cooper's Surgical Dictionary, article Fracture of Pelvis. Ed. 1838.

* Si l'on reconnaît des fragmens dont le déplacement et l'enfoncement dans les parties voisines causent des accidens graves, comme par exemple, une esquille des pubes ou de l'ischion, qui seroit enfoncé dans la vessie, ou dans le canal du l'urethre, en general, on empêcheroit totalement l'émission de urine, si l'on ne peut parvenir à operer la réduction, par des manœuvres qu'il est impossible de décrire, on ne peut se dispenser de mettre les esquilles, de decouvertes par l'incision des parties molles.—M. et. Chirurgicales, tom. iii. 156-7.

fractures of the pelvis; for in that case we lay open the injured part of the bone to the access of the atmosphere; this, however, is often unavoidable, and forms no argument in favour of the procedure recommended by Boyer, which we believe is more suppositious than the result of actual experience.

If it be conceded that from the mode in which fractures of the pelvis are generally received, the fragments, if displaced, are usually *beaten in*, the pelvis being narrowed, the principle is, I think, established, of attempting to widen the pelvis, or throw out the displaced portions by pushing out the ilia, as described, and carrying a finger or fingers within the cavity of the pelvis, feeling for any projections, and making a careful attempt to replace them. Beaten-in portions will not always be within reach of the fingers; expansion of the ilia will not always be required, or be effective; the fracture not always oblique, or the fragments pointed; displacement of any kind will frequently be absent, the fragments being held together by the mingled periosteum, muscles, fascia, &c.; but as a general rule, attempts to widen will be less likely to injure, and will more probably be advantageous, than compression, so commonly, and irrespectively of all conditions, advised.

Such we would suppose the proper principles of treatment, in whatever part of the pelvis the fracture exists, if there be displacement; and we have now to inquire what will be the best procedure after adjustment, or in those cases where, from the first, displacement could be detected.

The principal indication evidently is to keep the fragments at rest, which diminishes the risks of inflammation or puncture, tends to prevent inflammation and its consequences, and affords facilities for inducing and perfecting the processes requisite for ossific union.

But as we propose to discard, in all but a very few cases, the use of the belt or bandage around the fractured pelvis, the means hitherto principally relied on for keeping the injured parts in a state of repose, and as it is to be feared we do not possess any substitute for the supposed influence of the bandage, other than perfect quietude, we have to inquire what are the sources of motion in fracture of the pelvis, and how they may best be obviated. In addition to *those already dwelt upon*, there are

three causes of disturbance in cases of this kind; the gravity of the body and limbs, which acts more or less injuriously according to the position assumed; the action of the muscles arising from or inserted into the pelvis, a cause of disturbance which I have not hitherto alluded to; and, thirdly, direct motion, occasioned by change of posture in defecation, or to diminish the pain and other effects of long confinement in one position, &c. &c.

Fractures at different points of the pelvis, and running in different directions, are variously affected by position, and consequent gravity; probably the best guide for the posture which, in any given case, will combine the greatest advantages—which will best avert the influence of the weight of the limbs in dragging, or that of the pelvis and trunk in depressing, loose portions of the pelvis, upon any part of it resting on the bed—is that in *which the patient feels easiest*, as thereby we are shewn that then the fragments are not displaced, or that they are displaced and puncturing, straining, or lacerating the soft parts in the smallest possible degree. We would therefore allow the patient to recline on his back, or on either side, with the body and limbs flexed or extended, according as he felt most ease in the one or the other of these positions.

Rest and position of the fragments must likewise be much influenced by the active and passive contraction of the numerous powerful muscles of the trunk and limbs which arise from, or are inserted into, almost every part of the pelvis externally; while these are, in addition, assisted by muscles passing from the inside to the limbs, and by the strong levator ani lining the pelvis, and the other muscles more particularly pertaining to the organs of generation. The same remarks apply to the effects of muscular action as to those of gravity: they will indefinitely vary, according to the situation and direction of the fracture, its displacement, &c.; and although it cannot be feasibly doubted that the greatest amount of relaxation, in the greatest number of the muscles causing displacement and motion, is obtained in the state of semi-flexion, with the pelvis carried forward on the trunk, and the limbs on the pelvis, yet, for reasons similar to those we gave in relation to gravity, we would, on this

point too, be entirely led by the feelings of the patient, and would place him in the manner in which he obtained the *greatest degree of comfort*.

There will, if we have reasoned correctly, be many patients who will recline with most ease on one or other side, in the semi-flexed position; there will be others who will have most comfort reclining in the same posture on the back; and in the latter case, whether to counteract the effects of gravity or muscular action, we do not know of any contrivance equal, independently of its other recommendations, to the triple-inclined plane, or fractured, of Mr. Earle; to which the body resting upon a common mattress, and the limbs of the patient supported on a double inclined plane, such as that used in fracture of the femur, makes a near approach.

An equally difficult point to accomplish as the prevention or diminution of motion, is to preserve the skin from the effects of the long-continued pressure which the protracted confinement necessitates. In attempting to keep the patient perfectly at rest, we here, as in fractures of the vertebræ, run the hazard of inducing sloughing, and consequent ulceration, of the soft parts on which the weight is principally borne; but the hazard of sloughing is not so great in this description of injury, as the nervous agency is not necessarily or usually impaired, which, from the sloughing occurring only in the paralysed parts, is evidently its cause in fracture of the vertebræ accompanied by paraplegia.

Softness of the material on which the patient reposes is only beneficial by diffusing the superincumbent weight equally, and thus reducing it to its minimum over each point of the surface exposed; and this cannot better—cannot so well—be accomplished by any plan, as by placing under the pelvis, and other parts, if required, *a partially filled air pillow*.

To prevent the necessity for straining to expel the fæces, in which action the contraction of the muscles of the trunk, and those on the outside and inside of the pelvis, is strongly exerted, and motion and displacement produced, the exhibition of the gentlest laxatives will be proper; and the introduction, when the patient is about to evacuate the bowels, of a piece of cloth impermeable to moisture, for a short way

between the nates and the air pillow, will supersede the painful, troublesome, and injurious method of Boyer, who, for this purpose, recommends a girth to be carried below the pelvis; its extremities brought up in front, attached to a hook, and that again, by a rope, to a pulley fixed in the ceiling; and thereby the patient, he says, is enabled to elevate and suspend himself until a vessel can be properly placed and the bowels evacuated.

It is not my purpose to enter into the treatment required for the inflammation, suppuration, and extravasation, of blood, of urine, &c., so frequently accompanying fracture of the pelvis; and I will only remark that, in the employment of the antiphlogistic measures which may at first appear to be called for, we should not lose sight of the copious discharge, the hectic, and debility, which may supervene; and that here, as in compound fractures, and some other kinds of cases, we are placed between two imminent dangers; on the one hand, the advance of inflammatory action, and in averting that, the risk, on the other, of unfitting the patient to bear up against the exhaustion of suppuration, its attendant evils, and a protracted confinement.

EASTERN DISTRICT

OF THE

ROYAL MATERNITY CHARITY.

TABULAR VIEW OF THE CASES ADMITTED
FROM JAN. 1, 1831, TO DEC. 31, 1843.

To the Editor of the Medical Gazette.

SIR,

I HAVE thought it would be convenient to your readers to have, in a condensed and tabular form, the leading particulars embraced in the Reports of the Eastern District of the Royal Maternity Charity, which you have done me the honour to publish; I therefore inclose them for your use, if you think proper. I would refer to the MEDICAL GAZETTE for Jan. 31, 1829, for a summary of the chief difficulties that occurred in the same district of this Charity, from Jan. 1st, 1820, to Dec. 31st, 1827, during which period 19,439 women were delivered.—I am, sir,

Your obedient servant,
FRANCIS H. RAMSBOTHAM.

14, New Broad Street,
July 24, 1844.

It thus appears, that out of 35,743 deliveries, there were 386 cases of twins—1 in 92·6, or 1·06 per cent.; and 1 case of triplets.

That of the 36,131 children born,

18,610 were males—51·5 per cent.

17,521 „ females—48·5 „

or, in other words, that the excess of males over females was as nearly as possible 3 per cent.

That 35,096 were presentations of some part of the head, of which 141 were face presentations—1 in 248·9, or 0·4 per cent; and 6 were ear presentations—1 in 5849·3, or 0·017 per cent.

That 930 were presentations of the breech, or some part of the lower extremities—1 in 38·8, or 2·6 per cent.; and 105 transverse presentations—1 in 340·3, or 0·3 per cent.

That 33,868 were born living—93·7 per cent.

That 2,263 were born still—1 in 16, or 6·3 per cent.

That 166 women died either within a month after delivery, or from the effects of labour—1 in 215·3, or 0·46 per cent.

But that only 126 of these deaths could be attributed to a puerperal cause—1 in 283·67, or 0·33 per cent.

That 40 were placental presentations, either partial or entire—1 in 893·5 cases, or 0·11 per cent.

That in 206 cases the placenta was retained, or adherent, requiring the introduction of the hand for its removal—1 in 173·5, or 0·58 per cent.

That 116 were cases of accidental hæmorrhage—1 in 308·1, or 0·33 per cent.

That in 72 cases hæmorrhage took place after the delivery of the placenta—1 in 496·5, or 0·2 per cent.

That 31 were complicated with convulsions, either before or after delivery, —1 in 1153, or 0·09 per cent.; and 1 with apoplexy after labour.

That 38 women were delivered by craniotomy—1 in 940·3, or 0·11 per cent.

That 49 were delivered by the forceps—1 in 729·4, or 0·14 per cent.

That in 20 premature labour was induced—1 in 1787·1, or 0·06 per cent.

That there were 8 cases of ruptured uterus—1 in 4467·9, or 0·02 per cent.; 1 of ruptured vagina, and 2 of lacerated labium—1 in 17871·5, or 0·006 per cent.

That 4 were cases of breech presen-

tation, requiring instrumental delivery, —1 in 8935·7, or 0·01 per cent.; and that in 2 cases of twins, the second child was delivered by turning—1 in 17871·5, or 0·006 per cent.

That of the 126 deaths from puerperal causes, 56 were from hæmorrhage, either immediate or remote—1 in 2·25, or 44·4 per cent.

That the deaths from hæmorrhage, either immediate or remote, in proportion to the whole deliveries, were 1 in 638·27, or 0·15 per cent.; and in proportion to the number of cases of hæmorrhage, 1 in 7·9, or 12·6 per cent.

That there were two deaths from convulsions, which came on after delivery—1 in 17871·5, or 0·006 per cent.

6 after craniotomy—1 in 6·3, or 15·8 per cent. of the cases in which that operation was performed; and 1 in 5957·16, or 0·017 per cent. on the whole number of deliveries.

3 after the forceps had been used—1 in 16·3, or 6·12 per cent. of the cases in which that instrument was employed; and 1 in 11914·3, or 0·008 per cent. on the whole deliveries.

That 20 women died of peritonitis—1 in 1787·15, or 0·05 per cent.

8 of hysteritis—1 in 4468, or 0·022 per cent.

2 of diffused pelvic inflammation—1 in 17871·5, or 0·005 per cent.

3 of common fever caught after labour—1 in 11914·3, or 0·008 per cent.

5 of pneumonia taken after labour—1 in 7148·6, or 0·014 per cent.

The table also shews, that of the 40 deaths not attributable to puerperal causes, 23 were from diseases of the lungs, of which 15 were confirmed phthisis; 1 of the larynx; and 2 supposed to be diseases of the heart.

That 6 women died of typhus fever; 4 of Asiatic cholera, then raging; and 2 of scarlet fever,—all caught during pregnancy; 1 of dropsy, and one of a sloughing polypus of the uterus.

That of the 2263 still-born children, 373 were premature—1 in 6·06, or 16·5 per cent; and 173 were putrid at full time—1 in 13·08, or 7·7 per cent.

That 174 were breech presentations, out of 930 breech cases at full time—1 in 5·34, or 18·7 per cent.

61 were transverse presentations, out of 105 transverse cases at full time—1 in 1·72, or 58·1 per cent.

32 under placental presentations out of 40 cases—1 in 1·25, or 80·0 per cent.

60 under accidental hæmorrhage out of 116—1 in 1·92, or 51·7 per cent.

11 were delivered by the forceps out of 49—1 in 4·45, or 22·45 per cent.

37 were delivered by craniotomy.

12 under convulsions, out of 18, which came on before delivery—1 in 1·5, or 66·6 per cent.

39 under very lingering labour—1 in 58, or 1·72 per cent. on the number of still-born children; and 1 in 929, or 0·1 per cent. on the whole number born.

9 under ruptured uterus or vagina—1 in 251·4, or 0·4 per cent. on the number of still-born children.

109 under prolapsed funis—1 in 20·7, or 4·8 per cent. on the number of still-born children, and 1 in 331·5, or 0·3 per cent. on the whole deliveries; and that 20 were monstrous—1 in 113·15, or 0·89 per cent. of the still-born; and 1 in 1806·5, or 0·05 per cent. of the whole deliveries.

MICROSCOPICAL EXAMINATION OF AN EARLY CORPUS LUTEUM.

By T. WHARTON JONES, F.R.S.

Lecturer on Anatomy, Physiology, and Pathology,
Charing-Cross Hospital.

(For the London Medical Gazette.)

ABOUT the middle or end of May last, Dr. Lee brought to me an ovary containing a small tumor, which he informed me had been sent to him along with the uterus, and accompanied by the following note:—

“Monkwearmouth, May 9, 1844.

“Dear sir,—I venture to encroach on your valuable time, to ask your opinion of the accompanying preparation illustrative of a point to which the medical world knows you to have paid much attention.

“Is the corpus luteum in this case a true or false one? It was taken from the body of a female upwards of thirty years of age. She died suddenly, and no accurate information could be gained regarding her last menstrual periods. Several medical gentlemen have examined the corpus luteum, and are so much divided in opinion about it, that they would feel deeply indebted to you to examine it, and favour us with your decision upon the question.

“I hope you will have the goodness

to excuse the great liberty a stranger thus ventures to take; but knowing your kindness, and having every confidence in your opinion, I have the honour to remain,

“Your obedient servant,

“HENRY O. BOWMAN, M.D.

“Dr. Lee.”

“P.S.—As the preparation belongs to a medical friend, who was so kind as to allow me to examine it, I shall feel obliged by your returning it with your decision. If it were mine you would be heartily welcome to it; indeed, I should have considered it my duty to have presented it to you.

“H. O. B.”

The preparation was preserved in spirits. A section had been made, dividing the ovary and the tumor-like body into two similar halves. The appearance which this section of the body presented was like that of a firm dark clot of blood, having in its centre an elongated membraniform shred, one end directed towards the interior of the ovary, the other towards the exterior. From this shred, which was smooth on its free surface, processes extended here and there, in a radiating manner, into the substance of the clot-like body.

Dr. Lee was disposed to consider the body in question to be what to the naked eye its general appearance seemed to indicate, viz. a clot of blood containing a flake of fibrin, from which the red corpuscles had separated. And on making a fresh section of one of the halves of the body, in the same plane as the first, Dr. Lee was strengthened in his impression that it was not a corpus luteum resulting from impregnation; for the appearance which presented itself was such, that the naked eye could not well recognise it to be any other than that of a clot of blood.

On carefully tearing the clot-like body, however, under water, I found that it did not comport itself in the same way that a mere clot of blood would have done. I saw that the processes which radiated from the central membraniform shred into the substance of the clot-like body were filamentous, like what is observed in true corpora lutea. Besides this, I found that the proper substance of the clot-like body tore in a fibrous-like manner—the fibres extending from the central membrane to the circumference of the body.

I therefore stated to Dr. Lee that I suspected that he was mistaken as to the nature of the body, and that in fact it was a true corpus luteum in a very early stage; but that, considering the gravity of a decision on such a point, no conclusion ought to be come to until the body had been subjected to a most careful microscopical examination,—without which, indeed, any decision would be mere guess-work.

Dr. Lee coinciding in the propriety of this, gave over to me one-half of the ovary, and of the body in it, for microscopical examination; and the following is the result:—

The body in question is of a lenticular form, about six-tenths of an inch in diameter, and about four-tenths thick, and projects on the surface of the ovary by somewhat more than half its diameter. The prominent part being covered merely by the indusium of the ovary, the dark-brown red colour of the body shines through.

Examined microscopically, the central membranous shred was found to present the following structure:—

1. On its free surface a fine film of tessellated epithelium. 2. Invested by this epithelium was a stratum of finely interwoven transparent fibres, with dark contours, somewhat like elastic tissue. 3. Outside all was a layer identical in structure with the stroma of the ovary; the same structure as that composing the principal thickness of the walls of Graafian follicles.

The membranous processes possessed a similar structure, and were found to be continuous with the stroma of the ovary. That part of the body next the substance of the ovary had, by its pressure, so condensed the stroma at the place, that the latter looked somewhat like an external capsule sending processes inwards, which met and interwove with those sent outward by the central membranous shred. But that this appearance of external capsule was the result simply of matting of the stroma of the ovary by pressure, is shown by the circumstance that it was absent at the peripheral part of the clot-like body, there being there, as already said, merely the indusium*.

As to the microscopical characters of

* A corpus luteum turned out of its nidus in the stroma of the ovary may still retain an appearance of a capsular investment, but this obviously depends on the circumstance, that the matter forming the corpus luteum is infiltrated

the clot-like matter itself:—this was found to consist of granulous corpuscles, somewhat like so-called compound inflammation globules closely aggregated, and red blood corpuscles interspersed amongst them. The latter had lost some of their colouring matter, but the granulous corpuscles were tinged red, as if they had imbibed it.

The conclusion which is to be drawn as to the nature of the body from this investigation is, that it is a true corpus luteum* in an early stage; that the central membranous shred is the wall of the Graafian follicle, from which the ovum had escaped; and that the clot-like mass (which would have by and by acquired the characteristic yellow appearance of the corpus luteum, traces of which, indeed, could in some deep places be detected), together with the membranous processes extending through it from the central shred to the stroma of the ovary, is the stroma surrounding the Graafian follicle infiltrated with bloody-looking matter.

I say *bloody-looking*, for although it is certain that there is some blood present, it remains a question what sort of matter the granulous corpuscles were developed from—blood effused in substance, or exuded lymph?

Into this question I will not enter; but for some observations bearing on it, and on the nature of the organization of corpora lutea, I beg to refer to my "Report on the Changes in the Blood in Inflammation, and on the Nature of the Healing Process," in the last number of the British and Foreign Medical Review.

Before concluding this paper, I take leave to glance at the following questions:—

1. What determines the effusion of the matter from which a corpus luteum is developed? In answer to this it might be suggested, that in consequence of coitus, a reflexion takes place on the vessels of the ovary, and congestion is thus produced in the walls of the ripest Graafian follicle, and in the stroma around. Effusion of blood, and probably exudation of lymph, follows.

in a cellular tissue. The same thing is seen in the case of the wax of injection which has been extravasated into the cellular tissue, where it is turned out.

* See my "Report on the Ova of Man and the Mammifera before and after Fecundation," in Brit. and For. Med. Review, Oct. 1843.

According to this view the formation of a corpus luteum would be quite independent of the contact of seminal fluid with the ovary or ovum, and consequently independent of impregnation. And that it is so has been already established, as regards the lower animals, by the experiments of Haighton and Blundell on rabbits, viz. that though by obliteration of some part of the female genital passages, the access of semen to the ovary was prevented, still Graafian follicles were observed to have burst, and corpora lutea formed *post coitum**.

The same circumstance appears likely to have held in the case of the woman whose ovary forms the subject of the preceding observations, for Dr. Lee informs me that the fallopian tube of the same side was diseased and contracted, if not obliterated, and that the uterus had undergone none of the changes usually observed in its cavity and cervix after recent impregnation.

2. If in the human female Graafian follicles burst periodically, independently of coitus, why is there no corpus luteum left? The explanation which might be given of this is:—

By a slow, natural, and regular process, a Graafian follicle matures, points, bursts, and is evacuated like a small healthy abscess or pimple, and like this, the part quickly cicatrizes.

A Graafian follicle at the time of coitus not happening to be in this fully mature state, its bursting is hastened by the process of congestion, and exudation and extravasation, above described; but when burst, the lymph and blood in an altered state remain for a while in the form of a corpus luteum, which may thus be compared to the hard base of an abscess evacuated prematurely.

3. Though true corpora lutea, there is reason to believe, are formed only after coitus, impregnation may take place without the formation of a corpus luteum. How is this? The explanation which might be offered of such rare cases is this. Coitus may have chanced to take place at the very time when a Graafian follicle, having become mature, had spontaneously given way, and expelled the ovum. No congestion, exudation, and extravasation, would in this case take place, but the part would quickly close and cicatrize.

4. Lastly, what explanation can be given of the origin of false corpora lutea? To this it might be answered, that from some circumstance or other effusion of blood takes place into the interior of a Graafian follicle perhaps on the point of bursting spontaneously. This blood coagulates, and remains filling and distending the Graafian follicle, even although its walls may have subsequently given way.

But besides this effusion of blood, an exudation of lymph takes place on the inner surface of the walls of the Graafian follicle, in consequence of the irritation produced, which, becoming organized, presents the same yellow appearance as the substance of the true corpus luteum formed outside the walls of the Graafian follicle.

In conclusion I would remark, that, though *physiologically* one may be permitted to speculate, as I have done, on the relation between the occurrence of corpora lutea in the ovaries and preceding coitus, it would be rash and unwarrantable in any one to pronounce positively, from the occurrence of a corpus luteum in the ovaries, that coitus had taken place. The discovery of an ovum in the uterus, *in process of development*, could alone, in the present state of knowledge, warrant such an affirmation in a court of law. But, on the other hand, the absence of a corpus luteum could not warrant the affirmation that coitus had not taken place.

ON THE
PRESENT STATE OF CRANIOSCOPY,
UPON A SCIENTIFIC FOUNDATION:

A Lecture delivered at Leipzig, on the 3d of February, 1844,

By DR. C. G. CARUS,
Medical Privy Councillor, and Physician in Ordinary to His Majesty the King of Saxony, &c. &c.

TRANSLATED FROM THE GERMAN,
By J. C. H. FREUND, M.D.

(For the London Medical Gazette.)

Preface by the Translator.—The reason that induced Dr. Carus to yield to the repeated wishes of his friends to see in print this lecture, was no other than his deep conviction that its publication would tend to establish, in a wider circle, correcter views of a sub-

* See "Report on the Ovum of Man and the Mammifera," *et supra*.

ject which, the better its real importance is understood, the greater will be the attention bestowed upon it.

The lecture was not originally intended for publication. It must be confessed that within the limits of one lecture it was impossible for Dr. Carus to display the quantity of material he had collected, or to enter into a very close consideration, or any perfect explanation, of his views, which, founded as well upon the history of the *Psyche* as upon the anatomy of the body, may be conceived as requiring some space for their full development.

Dr. Carus expects that the plain and simple line of reasoning which he has followed in his lecture, will afford no less satisfaction to the scientific but unbiassed mind, than enlightenment to those who are neither acquainted with physic nor anatomy; for every thing like tedious detail has been purposely avoided.

The different works that furnish a more extended knowledge of Cranioscopy are pointed out in the course of the lecture; and Dr. Carus intends to seize every opportunity, upon future occasions, of further elucidating the subject, of cultivating it more extensively, and of rendering it more variously practical.

The interest which I have long taken in the subject induced me some years ago to translate Dr. Carus's work on Cranioscopy, published 1841, but I never laid it before the public. During the late sojourn of Dr. Carus with his Majesty the King of Saxony in London, I had the honour of his personal friendship, and many opportunities of conversing with him on the subject of cranioscopy. On informing Dr. Carus of my having made a translation of his earlier work, he advised me to publish a translation of his lecture given at Leipzig, as it conveys a clear view of the subject even to those unacquainted with anatomy and physiology. I have followed Dr. Carus's kind advice; and in laying it before the public, I have to crave indulgence for many Germanisms, which I know must present themselves to the English reader.

I wish especially to direct attention to one point: the words *Geist*, *Seele*, and *Psyche*, occur throughout the original as expressing simply the animating principle of the brain, whether in man or animals; and I use the term

"psyche," and "psychical," as meaning that animating principle, and nothing farther.

ON SCIENTIFIC CRANIOSCOPY.

Old Theophrastus, the pupil of Aristotle, and so famous for his great knowledge of man, says in the introduction to his work on Character: "I am often surprised, and, in spite of every possible inquiry which I have instituted upon the subject, I never could make out how it happens that the Greeks so little resemble one another; and yet their mode of education and of living is alike, and the climate of Greece herself is in all parts the same." We ought to apply this remark more generally, and say, that of all the wonders commonly left unobserved, or little noticed—wonders which daily surround us, and of which we ourselves form part—the most remarkable is that of the many millions of human beings now inhabiting the earth, of those who for thousands and thousands of years have passed away in successive generations, and of those who are to come in future times, there never have been, and never will be, two men thoroughly and completely alike.

This boundless variety in organic life, which can be seen in whatever direction we trace it—this manifold diversity, of which Leibnitz says that it never allows two leaves of the same tree to be precisely similar—prevails in the human organization with grand and unlimited freedom.

From the earliest times, therefore, the necessity became evident of introducing into this endless variety in nature, certain orders, distinctions, and subdivisions, and there was a constant endeavour to fix upon criteria, so as to enable us to recognise, distinguish, and as it were to decipher the different races of man, tribes, and families, and finally to learn how far individuals differ from one another according to their physical, psychical, and ethical or moral peculiarities. There was in general no difficulty in re-making a system of outward signs or symbols (*Symbolik*) so as to distinguish the negro, the most strongly marked class of the human race, and which I in my Physiology have called by the name of "*nocturnals*" (*Nachvoelker*), from the true European, the most strongly

marked class of the "*diurnal*" tribes (Tagvoelker), and the latter from a very extensive group of "*twilight*" genera (Daemmerungs-Voelker) in the east and west; and finally, it was easy to create a distinction between the idiot with his head either stunted in growth or enlarged by dropsical effusion, and the noble and the well-developed head of the man of the world or of letters. The features for this purpose were soon made out; but the more details were entered into, the finer the distinctions in the outward appearances that were sought after, so much more difficult did the undertaking become. The most astonishing circumstance was the eagerness with which external marks and signs of all kinds were grasped at. At one time the distinctive marks were taken from the features of the face, at another they were sought for in the whole organization of the individual; some supposed them to be latent in the form and lineaments of the hand, others in the difference in shape of the head; and, indeed, there might be some truth in all this, for every individual creature, and especially every human being, is not only peculiarly formed and organised in some one part or other, but the same peculiarity pervades all, inheres in every thing: with a hand of such and such a shape there we find exclusively such and such a face, and such and such a head, no other; every organism is but the true expression of a particular idea, and therefore must be thoroughly the offspring of the whole, and be in harmony with *itself*.

The difficulty in recognising perfectly this congruity, rests chiefly with *our* short-sightedness. The ancient artists were the first who practically succeeded in obtaining definite results in expressing the individuality of different forms; they observed very acutely the varieties of man as regards race, sex, and personality, through the peculiar conformation of limbs, body, and head, and imparted this character to their statues. This was well understood by the genius of the common people, who in such things appreciate at first, half unconsciously as it were, but therefore, and subsequently, with all the clearer understanding.

Let any one remark the difference in the trunk and limbs, in the head and countenance, of a Jupiter, an

Apollo, a Hercules, a Faun or Silenus, and he will not then deny that the Greek artists possessed a knowledge of the outward signs of human organisation, not less wonderful and striking, than any one thing for which we are indebted to that remarkable, and highly favoured nation, in poetry, the arts, or philosophy. With all this, however, the light diffused by scientific knowledge was still wanting; they were conscious that a different meaning was attached to this and to that, but a closer argument it never entered into their minds to attempt. Every thing that has been said of the different regions of the human skull partakes of the same uncertainty that we see in earlier times pervading the writings of Aristotle. Gordon, a Scotchman, and professor at Montpellier in the 13th century, following his predecessors, ascribed certain faculties of the mind to certain parts of the head; and he believed that a higher development of this region of the head bespoke a higher development of that mental faculty; but all this was said without any sufficient scientific reason.

The first traces of sound conclusions in regard to the meaning of different shapes of the head, and founded on scientific principles, are met with in the books of Giov. Baptista Porta, who, writing in the 16th century, supported his assertions partly by "comparing different forms of head in different animals, with those of well-marked human beings." But in spite of all this, no important results could be come to so long as the state of physiology had not led to any definite conclusions relative to the formation of the brain, or the development of the skull.

Dr. Gall, a German (born 1757, died 1828), was the first who laid a certain scientific foundation for the doctrine of symbols, as applied to the formation of the human head. At one time he directed his acute powers of observation to convince himself that certain forms of the head correspond in a most remarkable manner with certain peculiarities in the intellectual (*gemüthlich*) and active development of different persons; at another time he occupied himself in scientifically dissecting the human brain; and by making use of a more genetical method, he came to clear conclusions on the formation of many parts of that organ by plication,

and proved how absurd the method was that had been used up to that time by common and merely empirical anatomists, who satisfied themselves with dissecting the brain in slices as if it were a loaf of bread. It was the same with their description and nomenclature of the parts. Finally, Gall was the first who asserted that the brain is to be regarded as a higher development of the spinal chord, as if indeed it were a spinal chord diverging at the top, like the unfolding of a flower. It is to be regretted that at the time when Gall was occupied with these inquiries, viz., between the 80th and 90th years of the last century, the doctrine of the development, structure, and meaning of the organization, was very much in arrears. Happily, the progress which science has made in these respects during the last four decennials, and especially in the two last, has been very great.

The application of the microscope has not merely revealed a new world around us, in the same manner as the telescope has brought to view the heavenly bodies, but it has caused a world of new organizations to spring up within ourselves, especially as regards the subject in question, and of which neither Albinus, Haller, nor Soemmering, could have had any idea.

From the same cause Gall wanted material in investigating the structure of the brain and skull; and in his attempt to found a system of symbols he unfortunately did not content himself with merely collecting observations, and constantly comparing them with one another, in order to find out what sort of structure is usually met with in the head of this individual character, or that, &c., but he lost himself so far as to bring this most imperfect substratum to a kind of system, which he even sought, in his lectures from 1796, to submit, as it were, to the judgment of the public at large. Hence it happened that a multitude of unlearned men, who were unacquainted with the necessary preliminaries, not only made themselves masters of the system, but pretended to cultivate and to diffuse the same; and thus was brought to light the scientific monstrosity called Gall's Doctrine of Organs, in which it was asserted that the faculties of judgment, and kind-heartedness, the talent of painting, and the sense of locality,

theosophy, and other powers, were engrafted upon or connected with small portions of the surface of the brain, just as we are told, in the fables of old, that certain spirits remained incarcerated in the narrow fissure of some mighty oak. In fact, these opinions were too absurd not to be repulsive to all men of science; they were even of such a nature that they necessarily gave rise to a kind of disgust, and from this it followed that even the important conception, which is owing in a great degree to Gall alone, has been lost sight of, and that the doctrine of symbols has been allowed to fall to the ground as something hypothetical and superstitious. It was quite a different thing with the unscientific members of the community, who, not being aware of the great mistakes, were kept alive to the doctrine by the particle of truth contained in it, and which, in spite of all opposition, they acknowledged more by their feeling and instinct than by their intellect and faculties of comparison; and thus it was that to a certain degree they acknowledged the importance and signification of the outward structure of the skull in reference to corresponding psychical peculiarities, and preserved the idea in life and literature: yes, in spite of all their objections to the one-sided view of the so-called phrenologists, the public could not be persuaded to refuse some belief to this doctrine; and the opinions of Gall again and again rose to the surface, and even at the present day they are defended unfortunately by party men, who are about as capable of giving due weight to the importance of the subject as that Hungarian nobleman who, after he had attended Gall's lectures, purchased a collection of skulls, and, upon one occasion, shewing (triumphantly) to his friends two skulls which he regarded as important acquisitions, of which one was supposed to be that of Rakossi, the great revolutionist, replied, when asked by some one present "and whose is the other?" pointing to the skull of an infant, "that is the skull of the same Rakossi when he was a child."

I readily confess that it required a long time before I could bring myself to take any interest in this subject, although for thirty-four years now I have been a zealous and active follower of anatomical, physiological, and medi-

cal science. I was too much in the habit of pursuing the light of close scientific reasoning to pay any attention to these hypotheses of the abstract doctrine of organs. Whilst working out my *System of Physiology*, I was led to trace once more, step by step, the meaning of the osseous structure, and thus I became cognizant of the truth, that if, by following more closely the relation between the nervous system and psychical life, it should become apparent that there is, originally, a peculiar psychical meaning allotted to every larger portion of the brain, it must also necessarily follow that that division or portion of the skull or skeleton of the head which bears reference to such a division, must afford a sign, a symbol, indicative of the degree of development of that portion of the brain which is contained in the same.

While I here took hold of the thread, for the purpose of going the right way in this great labyrinth, and while I felt from thence all the love and zeal for closer and clearer inquiry into that particle of truth of which Gall had a slight conception, I was obliged to confess, at the same time, that it is one of the most difficult tasks to be solved by morphology and physiology, that it is a subject which—thus we may follow it up to its height and find its application to real life—requires a thorough knowledge of all the facts and experiences offered by physiology and pathology; a subject, finally, the further cultivation of which ought never to be sought for from the dilettante and unprofessional men. I therefore beg leave to call to mind that this essay of the real results of a new and scientific craniology must not be looked at as an attempt to give that information which will at once enable us to ascertain the peculiar faculties of the mind, the propensities and inclinations belonging to any individual, merely by observing and touching his skull; but I wish it may be regarded as an account of all that I have found is possible to collect upon the doctrine of symbols by a strictly scientific examination of the structure of the brain and skull of the subject.

There can be no reasonable objection to lay these results before the public: we see that the same is done with the progress recently made in natural phi-

losophy, astronomy, and physics; and surely nobody will suppose that all who attend to these subjects become astronomers and natural philosophers, or men of science.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

A Practical Treatise on the Diseases of the Testis, and of the Spermatic Cord and Scrotum; with Illustrations. By T. B. CURLING, Lecturer on Surgery, and Assistant-Surgeon to the London Hospital, Surgeon to the Jews' Hospital, &c. London: Longman and Co. 1843. 8vo. pp. 542.

WHEN we read the announcement of this work, we considered Mr. Curling a bold man to engage in such an undertaking. The subject, we imagined, had been so fully worked out by the great master of modern surgery, and so recently revised by Mr. Bransby Cooper, who favoured the profession with a new edition of his uncle's work so lately as 1841, that we had our doubts whether or not Mr. Curling could shew good cause for bringing his name thus conspicuously in juxtaposition with one which, for generations to come, must be the cynosure of English surgery. Yet a little reflection served to convince us, that it was unfair to prejudge Mr. Curling on such grounds, and we determined to reserve our opinion until we should have the work before us. There would be little progress made in science were the industrious cultivator to be deterred in his investigations by the consideration that the highest talent had already, and that but lately, been devoted to the same subjects. Fortunately, all history goes to shew, that the brilliancy of one man's talents and achievements only serves to call forth latent power in others, who might else have lived their appointed span without evincing one spark of the slumbering fire within them. We might adduce examples illustrative of this view in all departments of life,—in the senate, in the field, and in science; in none could we find more striking examples than in medicine.

Mr. Curling is already well known to the profession through his excellent work upon Tetanus; and the connection which he has so long enjoyed with the London Hospital has afforded him great opportunities of prosecuting his researches on the pathology of the testis. The work before us will, we believe, add much and deservedly to Mr. Curling's reputation as an author; it affords ample proof of the able, diligent, and steady manner in which he has applied himself to his assumed task. We are told in the preface that his attention has been directed since 1835 to the subject of the morbid anatomy of the testis, and that he has lost no opportunity of studying the pathological changes to which this organ is liable.

The work has been divided into three parts, comprising the Anatomy of the Scrotum and Testis, the Diseases of the Testis, and the Diseases of the Cord. Of these, that section devoted to the diseases of the testis occupies the largest portion of the volume, and is the one which will, in all probability, be most interesting to the practitioner. Like a sound pathologist, however, Mr. Curling has, by commencing with the normal anatomy, evinced his opinion that a person had best learn to appreciate healthy tissue and development before he devotes his investigations to the wider and more difficult field of morbid structure.

The anatomy and descent of the testis are so fully treated of in works upon anatomy and physiology, that we need do no more with reference to this part of the volume before us, than state our impression that Mr. Curling has executed it in an able manner, more especially as regards the progress of the organ towards the scrotum, on which subject he entertains some views peculiar to himself, and which have received the sanction of some other modern authorities. He adheres, we perceive, to the ordinary term "descent," in allusion to the gradual alteration in the site of the testicle; but we wonder that, with his usual accuracy in the use of language, he does so. During fœtal existence the course taken by the organ is as much of an ascent as the reverse. The term descent was doubtless used in former times to imply, that the weight of the organ during the upright attitude of the body

caused it to descend into the scrotum—a vulgar mechanical notion, which readily gains credence with those who do not know better. Our author has demonstrated that the true motive power which induces the change in question is in all probability in the gubernaculum and cremaster muscle, and breaks a lance with Hunter and Meckel on the subject, by way of shewing that these distinguished anatomists had not sufficiently appreciated the different attachments and changes of these structures. If, then, the testicle be acted upon in the mode described by Mr. Curling—and we think highly of his views on the subject—we conceive that it would be better at once to adopt some other term than in general use.

But our readers, like ourselves, will doubtless be most anxious to know something of the section on diseases of the testis; and we therefore hasten onwards. No less than eighteen chapters are devoted to this portion of the work. The first, which relates to "Congenital imperfections and malformations," is full of interest both to the physiologist and surgeon; and here, as in other parts of the volume, we have been much pleased with the able manner in which the author keeps up the practical character of the book. After describing the condition of the testis when, unfortunately, it remains in the abdomen until to the age of puberty, and pointing out that the organ may nevertheless be developed to the full performance of its functions, he introduces some excellent remarks on the propriety of arresting the progress of the testicle towards the scrotum in those instances where it seems disposed to move during the adolescent period. Unless the organ has made advances in very early life, there is every probability that it will not pass fairly into the scrotum, and hang loose and free as in the perfectly formed man. Mr. Curling has well pointed out the danger of such a condition, both with reference to the "liability of the gland to injury and disease when retained in the groin," as also "the tendency to produce rupture." A rupture under such circumstances would differ in no material respect from a congenital one; and to obviate all such annoyances and dangers, our author recommends the use of a truss on the groin, to pre-

vent the testicle passing into the inguinal canal. In such practice we are of the same mind; and should the gland not appear before the age of twelve years, we should unhesitatingly advise the application of a truss on the first intimation that any movement was about to take place. Such an indication would be a fair proof that the organ was well developed, and the patient or his friends should, under all the circumstances, rest contented with things as they are.

In the chapter on hydrocele, Mr. Curling has probably done more for the practical character of his work than in any other portion of it; and as it would be impossible for us, with our limited space, to follow him throughout the whole of the sections, we feel bound to award our approbation, in the strongest terms, to most parts of this chapter. Where so much has been done for a single disease, it would be hard to find two men who should agree on all; but the general tenor of our author's doctrines are, in our opinion, such as no one can dispute. We select the following passage as an average specimen of the style, and our practical readers will at once perceive the value of the quotation:—

“To distinguish simple hydrocele from malignant disease of the testis is not difficult, unless the parietes of the sac containing fluid be much thickened. But when the cyst is so thick and dense as not to admit the passage of rays of light, a careful examination is necessary to enable the surgeon to form a correct opinion. Like hydrocele, the diseased testis may present a tumor of an oval form, which has commenced at the lower part of the scrotum, and has formed gradually and without causing pain. It may also fluctuate indistinctly, and remain of uniform size under pressure, and in all positions; and the spermatic cord may be felt above it in its natural state. In lightly balancing, however, the tumor in the hand, the diseased testis feels heavier than a hydrocele; and its external surface is seldom so even and uniform as, nor does it often assume the pyramidal form of, a hydrocele. On pressing the part occupied by the testis, if the tumor be a hydrocele the usual pain is experienced; whereas if it be a malignant swelling of a large size, the disorganisation is attended

with loss of the natural sensibility of the gland. If the slightest transparency can be detected on inspecting the swelling through a tube in the manner explained (and I have not met with many cases of hydrocele in which transparency could not be perceived when the tumor was examined in this way), all doubt becomes removed. But in an obscure case the surgeon might introduce a grooved needle or a trocar into the swelling, when, if the case be hydrocele, the escape of fluid would at once manifest the nature of the disease. I once met with an indolent tumor of a small size in the scrotum of an old man, which was so irregular and uneven, felt so solid, and weighed so heavy, that it was impossible to determine exactly whether the swelling was occasioned by a morbid enlargement of the gland, a hæmatocele, or a hydrocele with the sac unusually thickened and indurated. The age of the patient was such as to put an operation out of the question. He subsequently died of disease of the chest; and, on examination, I found the tumor to consist of a hydrocele, the sac of which was cartilaginous and much thickened, and the contents a soft oleaginous kind of substance, consisting chiefly of cholesterine. The nature of such a swelling could only have been clearly ascertained by a puncture. The difficulty of diagnosis, in cases of cartilaginous thickening of the tunica vaginalis, has been attested by Dupuytren. In a case of enlargement and induration of the left testicle attended with lancinating pains in the groin and loins, and much emaciation, symptoms expressive of scirrhus disease, and unaccompanied with any sign indicative of hydrocele, or scrofulous or venereal disease, this distinguished surgeon, to avoid all chance of error, made an exploratory puncture. The result showed the prudence of this precaution; for, instead of schirrus, the case was found to be a hydrocele, with cartilaginous thickening of the tunica vaginalis.”

There is an excellent historical sketch of the different methods of effecting a radical cure; and, as might have been expected, Mr. Curling gives the preference to injection as a general practice, but at the same time points out examples where the method fails; and in such instances he seems to recom-

mend the seton, or incision, as the ultimate resource. It will perhaps be best to let the author speak for himself on the subject:—

"A careful examination," he says, "into the merits of the various modes of effecting the radical cure of hydrocele, fully establishes the superiority of the treatment by injection. The great error formerly committed by surgeons in endeavouring to excite a high degree of inflammation arose from a mistaken view of the object to be attained; for not perceiving that the exundant secretion could be arrested by altering the action of the vessels of the part, they thought it necessary to obtain the obliteration of the natural cavity, which, moreover, they endeavoured to effect by producing suppurative inflammation of the membrane, instead of by the milder process of adhesion. In recent days, surgeons have sought to improve the treatment of hydrocele by reducing the amount of inflammation to the lowest possible standard, and have nearly fallen into the opposite error of suggesting plans too mild to be efficacious and sure. Injection has now been largely tried in this and other countries; and experience warrants us in asserting that though it is not an infallible remedy, of all the plans hitherto practised it combines the greatest number of advantages. The pain attending it is slight; its effects are mild, and at the same time tolerably sure; if properly performed, it is free from danger; and it frequently succeeds without altering the natural condition of the parts. I know it is a question whether the cure by adhesion, though less perfect than that in which the disposition merely of the vessels is changed, is not upon the whole preferable. In the latter there is a possibility, if not a probability, of a relapse at some future period, many of the causes conducing to hydrocele still remaining; whilst the inconvenience produced by an impediment to the free movements of the testis, in cases cured by adhesion, is regarded as too trivial to be any disadvantage. But, in the absence of data showing the degree to which the disease is liable to return after the cure without adhesion, I feel perfectly satisfied with such a result, and much prefer leaving a patient exposed to the doubtful chance of a relapse, than subjecting

him to severer treatment in order to make sure of exciting sufficient inflammation to secure adhesion and obliteration of the sac. Injections, however, are not capable of effecting a cure in every case, nor are they adapted for every constitution. The judicious surgeon, therefore, whilst resorting to them as his ordinary remedy, will be prepared to avail himself, in particular and difficult cases, of other means more certain in their effects, such as the seton and incision.

In his own practice Mr. Curling has used lime-water as an injection, in preference to the dilute port wine recommended by Sir James Earle, or any of the numerous fluids which have been used for the purpose. He does not claim any peculiar virtues for this injection, and perhaps the most that he says in its favour is to this effect:—"Though a mild injection, it usually excites sufficient irritation to cure the disease; and I have rarely had occasion to resort to fluids of a more stimulating nature."

We are of opinion that Mr. Curling has not done full justice to the still novel method of using iodine injections. He states that "these were first tried by Mr. Martin, a surgeon in India;" and that in the Native Hospital in Calcutta, during a period of little more than seven years—from March 1832 to December 1839—2393 cases were subjected to this treatment, wherein the failures were rather under one per cent. The result he regards as "remarkably successful;" yet "I much question," he says, "whether this injection possesses such superior advantages as have been represented by many who have employed it:" "it is a valuable and efficacious mode of treatment, and perhaps as successful as any other injection which has been resorted to for the cure of the disease." Velpeau, Ricord, and others on the continent, strongly advocate the use of iodine injections, and the practice is becoming common among our own surgeons. Mr. Busk, of the Dreadnought, and "several" of Mr. Curling's "medical friends," who have tried iodine injections, have given their assurance that, "though usually successful, they did not answer better than port wine;"—and, for his own part, Mr. C. states that "he has found injections of lime-water answer so well, that he has had no inducement

to make trial of new remedies:" yet what performer with solutions of port wine; alum, zinc, spirits of wine, with warm or cold water, air, chlorine gas, or lime-water, can adduce any thing like the success recorded of Mr. Martin's practice? We recommend Mr. Curling to give Mr. Martin's method a fair trial, and that he with others will bear in mind, that success in altering the condition of the tunica vaginalis was not the only reason that weighed with Mr. Martin in laying a statement of his practice before the profession. The *smallness of the quantity of fluid necessary for the due performance of the operation* was particularly alluded to by that gentleman, as a safeguard against an accident which undoubtedly has occurred but too frequently, viz. injection of the fluid, port wine or any other, into the cellular tissue; and, moreover, *permitting the small quantity of fluid to remain in the bag of the hydrocele*, was another feature in the practice alluded to which should not be overlooked. We are too familiar with the effects of port wine in the cellular tissue of the scrotum, and what might be the effects of lime-water in a similar position, we shall not stop to inquire; but if, after giving any single practice, or all the methods known in Europe, a trial equal in amount to that whereby the iodine has been tested, and Mr. Curling still goes no further than the luke-warm approbation, that the practice is "perhaps as successful as any other," &c. (which words we ourselves have put in italics in the quotation in the preceding column), then shall surgery in all parts of the world have to boast of a success in the treatment of hydrocele hitherto unknown in the art. We confess that we have our suspicions when we hear of wonderful feats performed by native surgeons, in parts of the world where civilization has scarcely more than a footing; but it must be borne in mind, that though Mr. Martin was "a surgeon in India" when he tried this practice, he occupied a conspicuous position in Calcutta, and is now, we are happy to say, in London amongst ourselves, in honourable retirement, from a long, laborious, and eminently useful course of public service in our Eastern empire.

The sections devoted to "Congenital hydrocele," to "Encysted hydro-

cele of the testis," those to "Hydrocele of the cord," and especially that wherein "Complications of hydrocele" are considered, are all worthy of careful perusal by the practical surgeon; and the chapter on Orchitis is equally deserving of notice. Here no point of a useful character has, in so far as we can perceive, been omitted to be noticed; and the sixty pages on this very common malady may challenge comparison with any other in the volume.

Mr. Curling, we observe, is more than inclined to dispute the ordinary doctrine, that injections in gonorrhœa are a fertile source of swelled testicle; and it seems evident that the members of the profession are less afraid on this score than they were wont to be, for we know that the practice of using injections in gonorrhœa is becoming much more common than it was lately; and though we believe that in some instances the "inflamed cod" is the result of such treatment, we agree with Mr. Curling in recommending a more frequent and judicious use of this remedy for gonorrhœa.

The modern practice of compression, as introduced and recommended by Dr. Fricke, of Hamburg, receives the full approbation of our author; and though we were long loath to try it, we now freely profess our allegiance, and declare our conviction, that there are few cases of hernia humoralis, whether in the acute or chronic form, which do not readily yield to the careful application of straps. Mr. Curling gives excellent instructions in regard to the mode of using them.

The chapter on "Sympathetic and Functional Disorders of the Testis," calls forth our especial admiration. Throughout the whole volume Mr. Curling has evinced a manly style of treating all moral subjects which may be deemed professional at the same time; and though we question his ethnics on some points, we hesitate not to say that there is no single page which might not with propriety be laid before the youngest in the profession. In no part does our author shine more in this respect than in the chapter referred to. Here the subject of spermatorrhœa, which has lately attracted so much attention, is ably treated in a professional point of view, while he has carefully eschewed mixing his name up with those disgusting controversies which have lately

disgraced the pages of some of our medical hebdomadals. *Ne auctor ultra crepidam* might well be borne in mind by the parties alluded to, and we are of opinion that Mr. Curling has kept himself admirably to the limits of his own subject.

In the third part of the work, which is devoted to Diseases of the Spermatie Cord, we find little requiring particular comment. Perhaps the chapter on Varicocele is that which will attract most attention. The improved modern methods of dealing with the enlarged veins are all alluded to, and the results are shown to be such as to encourage further trials of some of the methods of obliterating these vessels. They, moreover, in our mind, serve to lessen that dread of surgical interference with veins which may truly be said to have been the bugbear of modern practice; for it seems that these vessels may be treated with compressors and ligatures with as much impunity as on the leg, where they have been so extensively destroyed within the last ten years. We are glad to see that Mr. Curling disapproves of the method of removing a portion of the skin of the scrotum in the treatment of this affection, for notwithstanding that it had the sanction of Sir Astley Cooper, and that it has been done by Key, Bransby Cooper, and other good surgeons, it has appeared to us almost as unreasonable as if we were to propose removing an elliptical portion of skin from over the course of the linea alba, to cure obesity.

We rise with pleasure from the perusal of Mr. Curling's work—not that we are glad at having arrived at the end of a task which it was our duty to perform, or because in the volume there is, as there must needs be in all professional works, much that is already familiar to the initiated—but because we can heartily recommend it to the practical surgeon. It would be folly to institute a comparison between it and the quarto volume of Sir Astley Cooper. The text is, in almost every respect, up to the present day; it embraces more subjects than the work of the deceased Baronet, and if it wants the imposing bulk and beautiful plates in the volume alluded to, it makes amends by its more portable and less costly form, while the graphic skill of Mr. Bagg has left little cause for regret at the absence of coloured illustrations. Mr. Curling's work does

honour to himself, to the name he bears (Blizard), and to that institution which fostered his early professional career.

“*Licet omnibus, licet etiam mihi, dignitates Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO

THE ROYAL COLLEGE OF SURGEONS OF ENGLAND, AND SIR JAS. GRAHAM'S MEDICAL PROFESSION BILL.

WE are as miserably ignorant of law as counsel usually and notoriously are of the probable issue of the suits in which they engage. We only know, that ever since the time of Henry VIII and Elizabeth, there has been great jealousy in the minds of the Commons of England of every thing in the shape of Royal Charters, and Letters Patent, conferring immunities and privileges on particular companies and individuals; and this to such an extent, that even the old charters of the Universities of Oxford and Cambridge were held to require confirmation by Parliament to render them valid and legal.

Sir Jas. Graham has shown a singular degree of shyness in regard to his Bill for the regulation of the medical profession. It was positively to have been laid on the table of the House of Commons on Tuesday last; but Tuesday came and went without the bill seeing the light;—the promise made for something like the tenth time during the present session to produce this bill was again not kept. We trust the Hon. the Home Secretary has no purpose to leave in the lurch those at the Royal College of Surgeons who have acted so far on the faith of his promise. Unless the supplementary Charter to that body be confirmed, we apprehend that the late election of Fellows which took

place in Lincoln's Inn Fields will scarcely hold good in law; and, indeed, when we look back upon the general features of that election, and survey the constitution of the electoral body, bearing in mind at the same time the object proposed in the recent changes, we almost trust that the Charter in its present shape will not be confirmed.

We, for our own part, were content with the old constitution of the College of Surgeons. There was a general feeling in the professional mind, however, that it required to be made more popular. The self-election practised by the Council, in particular, was viewed as highly objectionable; and it became imperative on that body to abandon this privilege. But where were they to place it? In the hands of the members at large? This would have been the natural, the easy, the obvious mode of proceeding; but the Council appear to have shrunk from this large measure of enfranchisement; wherefore, we own we do not understand; for a more sober-minded, more deferential, and more respectable body of men than the great majority of the members of the Royal College of Surgeons, does not exist on the face of the earth. There may be some half-dozen noisy demagogues or so, and as many blackguards, among us; but the spirit of the medical profession is essentially respectful, essentially conservative; and the popularity-mongers would have been lost in the legion of sober-minded middle-aged men—men between 30 and 50—who give its stamp to the profession in the world, and in whose hands is almost the entire medical practice of these countries. The Council shrank from the large, and, we venture to say, the merely *fair* measure—for every member of the College of Surgeons became so in virtue of the same amount of general and professional education, and after having honourably acquitted himself under the

same test of competency—and there was nothing for them but to contrive a distinction in grade, or to make a difference in the denomination of its members, to one of which should be confided the electoral privilege, whilst from the other should be withheld all voice in the management of affairs, whether in person or by representative.

We have already said, that we hold the idea of grade in the several branches of the profession of medicine to be inadmissible: different grades of physicians seem to us absurd; so do different grades of surgeons: he who is a physician or a surgeon can be, in our eyes, nothing more and nothing less. We therefore, with great deference to the many able men who are at this time members of the Council of the Royal College of Surgeons, venture to differ from them on the very original of the idea which has guided them: we cannot help viewing with alarm the distinction of the members of the College of Surgeons into Fellows and Licentiates; it seems to us as if a fatal stab were aimed through this, first at the prosperity of the Institution itself, with its noble appendages of Museum and Library, and next at the character and standing of the surgical profession at large in the public mind.

And then, if we descend from the theory of the affair to the practice, to the working of the machine, we cannot but see it as radically defective; the whole thing is so much out of joint that it must almost of necessity come to a stand-still. Who constitute seven-tenths of the potential electoral body of the College? The staff in esse or in posse of the London hospitals alone, one of these having, it may be, eight or ten voices out of the hundred which seat members of the Council. We do not say that these gentlemen are not the most proper men in the world to be entrusted with the powers just put

into their hands; we believe them to be in every way qualified by social rank education, and knowledge, duly to discharge the very highest duties; but they do not constitute the medical profession, they are a very small fractional part of the whole number who are legitimately members of the Royal College of Surgeons. One hundred and twenty of the very best still leave several thousands as good as they without equal privileges.

The Council ought to take heart from the behaviour of the mass of the members of the College ever since the recent changes were announced. The Council cannot be ignorant of the general—we had almost said the universal—dissatisfaction engendered in the mind of the medical profession, members of the College, by the new arrangements. But by the general body this dissatisfaction has been shown as is an indignity received from an intimate or confided friend—more in sorrow than in anger, more as something unexpected and uncalled for, and to be brooked in silence rather than vented in complaints. Without disparagement to those who have signed the address of remonstrance which purports to issue from the so-styled Medical Protection Society, we do not find the names of a large number of those whom we have been accustomed to regard as the representatives of all that is most respectable in our profession; we miss the names of several worthy men as taking part in the proceedings of late, who lent the society their voice and countenance at first. A sense of unworthy usage locked up in the minds of a majority is not insignificant; it ought not to be left to rankle there and by and by to find a tongue that may be dangerous.

The choice of Councillors on the 31st ultimo satisfies us that a great extension of the electoral franchise is indispensable; cannot be left restricted

to its present narrow limits. The character, and conduct, and social position of at least 300 additional respectable men will be required to give the system just instituted any chance of receiving the sanction of the general body of medical practitioners.

The bye-laws and ordinances, too, that regulate the admission to the Fellowship, appear to require revision; they are conceived in so stringent a spirit that they scarcely leave any man who has not a London medical education eligible to the dignity. More than this, they make it impossible for present members to achieve the dignity. This has already been perceived by gentlemen in various departments of the public service especially; we have heard of remonstrances from the Army and Navy medical departments, of petitions from the East India Company's medical officers, and we have just received the following one from the medical officers of the Horse and Foot Guards:—

To the Honourable the Commons of Great Britain and Ireland, in Parliament assembled, the Petition of the undersigned Medical Officers of the Horse and Foot-Guards,

Humbly sheweth,

THAT the recent Charter granted to the Royal College of Surgeons of England, a copy of which was lately laid on the table of your Honourable House, presses with peculiar severity on the officers of their department, nearly the whole of whom are by it deprived of those privileges they have hitherto enjoyed in consequence of an undue precedency granted to surgeons in civil life, whilst they will also be deprived in future of the hope of succeeding to offices of honour and profit in the College, whatever may be their ability, or the eminence they may have acquired in the service of their country.

Your Petitioners now appeal to your Honourable House in full confidence that their claims will be fully and favourably considered.

Your Petitioners whenever employed in the service of their country, either at home or abroad, have always endeavoured faithfully to discharge the duties

of their station, and have used every exertion to improve the practice of their profession.

Your Petitioners respectfully, but earnestly submit, that they should not, in consequence of being employed in the Public Service, be considered to have forfeited their civil rights as Members of the Royal College of Surgeons.

Your Petitioners humbly pray that your Honourable House will not confirm any measure depriving them of their hitherto acknowledged rights and privileges, without giving them an opportunity of being heard by themselves or counsel either at the Bar of your Honourable House, or in such other way as your Honourable House may be pleased to direct.

And your Petitioners, &c.

The task which the Council of the College of Surgeons had to perform became a difficult one from the moment that they took restriction into their scheme as an element. No system can by possibility stand, at the present day, into which a large measure of liberality does not enter. This infusion we miss in the new constitution of the College of Surgeons; and we venture to predicate, with full assurance of fulfilment to our vaticination, that it is altogether without the elements of even the ordinary stability of sublunary things, which ought to extend at least over some half century or so.

What precedes was written and in types, as may be conceived, before Thursday at noon, when we had the proof to revise, and a copy of the *Times* newspaper, in which we find that Sir James Graham has actually and at length laid his Medical Profession Bill on the table of the House of Commons. We can only lay the abstract of the Bill before our readers this week; next week we trust to be able to supply the provisions of the proposed act in detail. Our comment on the state of affairs at the College is not essentially altered by the introduction of the Home Secretary's measure,

so that we leave what we have written unchanged. The following is the *Times'* abstract of Sir James Graham's Bill:—

"Sir J. Graham moved for leave to introduce a bill for the regulation of medical practice. He was aware that some great authorities, among whom was Adam Smith, were adverse to any legislative interference with the medical profession; but the Legislature had, in fact, interfered from time to time, and the anomalies under the now subsisting law were many and gross. The bodies possessing power to grant a title to practise were extremely numerous, and required some central control. At present there was a sort of contest among them, in which they endeavoured each to attract students by underbidding one another. With respect to the mischiefs of quackery, he would not attempt to deal with them. There was a disposition among mankind to be cheated, as well as a desire to make money by cheating; and he was satisfied that no legislation could effectually combat these tendencies of human nature. He would therefore introduce no restraint upon medical practice; but he would endeavour to furnish some guarantee to the public, by confining public offices, medical and surgical, to educated practitioners, registered under the provisions of this bill. He proposed a general repeal of exclusive laws and charters, even the abolition of the exclusive right of the College of Physicians to grant licenses. His bill would establish a Council of Health of eighteen members, to be always sitting in the metropolis, of which he explained in detail the constitution, and in which he meant to vest a controlling power over the present licensing bodies. And he would insert a clause disabling all persons not registered, except those already in practice, from recovering any professional charges by law."

PENSION TO THE WIDOW OF SIR CHARLES BELL.

No one who knew Sir Charles Bell did not see him heart and soul in anatomy and physiology; he was the *beau idéal* of a cultivator of these elementary sciences. Sir Charles had also good taste in the arts of painting and design, and had moreover a ready hand with the pencil and the brush. The plastic arts were, in fact, the subjects upon which he loved to expand, and to which he made especial application of his science as a philosopher. He had no taste for the details or for the practice of his profession as a

surgeon—he even felt the advent of a patient as a sort of intrusion upon his privacy: however much he might have been in want of the guinea which the sick man had in his pocket for him, it signified not; he was busy cogitating the heads of his next lecture, or engaged with some point of profitless interest to himself, or to abstract science. He therefore always gave patients grudgingly the five or ten minutes which were necessary to win the money that was to keep the wolf from the door for the day. Of course such a man had no love of gold; of course he took no pains to win it; of course he lived poor, and when he died he left no provision for those, or for the one who had loved and cherished him, and shared his joys and his sorrows, and sweetened his labours, and been true to him through good report and through bad report, and watched with him to the last, and finally closed his eyes for ever.

It is much to be regretted that in this country there is no provision with suitable occupation for men of the stamp of Sir Charles Bell. England would gain glory by some arrangement of the kind. Sir Charles Bell was not fitted to scramble for the daily bread; and society, doing simple justice to herself, would have done wisely to have put him beyond the necessity of scrambling. He lived honoured, however; he made the world his debtor, and he earned a deathless name; but he lived, and he died, poor. Sir Robert Peel has had the honour of providing for his widow, by placing her on the pension list: Dame Maria Bell there stands for the sum of £100 per annum. A gentlewoman who has a clear £100 per annum is always independent, but we own we should have liked to have seen the sum larger; £200 would have been more like evidence of a due estimate of Sir Charles Bell's services to science. Miss Ann Drummond, sister of poor Mr. Drummond, who was so foully assassinated, has £200 per annum; and Dame Florentia Sale, wife of the hero of Jellalabad, has £500 per annum. These pensions are right and proper; we only do not like to see science standing at the bottom of the scale. Miss Drummond cannot have depended on her brother more completely than Lady Bell did on her husband; and if £200 seemed fair to the spinster, surely the same sum was not more than might have been awarded to the widow.

We are happy to see another zealous labourer in the vineyard of science—Robert Brown—properly considered in the list of pensions lately made public.

CLINICAL INSTRUCTION AT HANWELL LUNATIC ASYLUM.

Dr. CONOLLY, the senior and superintending physician of Hanwell, when Professor of Medicine in University College in 1830, drew public attention "to the importance of making medical men as familiar with disorders of the mind as with those of the body, and particularly dwelt upon the necessity of rescuing lunatics from those whose interest it is to represent such maladies as more obscure and more difficult to manage than any other." He moreover expressed a wish "that a clinical school might be established in every public lunatic asylum, in which, under certain restrictions, medical students might prepare themselves for their future duties to the insane."

In furtherance of these enlightened views, this truly accomplished and consistent man, now that he has the power, has proved the sincerity of his inclination. During three successive years, with the sanction and countenance of the Middlesex magistrates, he has given a short course of clinical instruction and lectures to a limited number of medical practitioners and pupils, on the more prominent subjects of mental maladies, and on the management and safe custody of lunatics.

The plan of the course has been as follows:—Tickets of admission were sent to the principal metropolitan hospitals—two to each of the larger, and one to the smaller, to be given to those pupils whom the authorities of the respective establishments might select. Qualified practitioners were admitted on application. These gentlemen went to Hanwell on Saturday, by the 9 A.M. train, and having entered their names in a book at the lodge, were met by Dr. Conolly and the assistant physicians Dr. Begley and Dr. Davy, who, to their great honour, entered most cordially into the plan. Dr. Conolly then made some preliminary remarks on the cases which had been recently admitted, or such as presented any very noticeable circumstance, and finished by directing attention to the cases in the asylum which were most fitted to illustrate the topic which he had chosen for the lecture of the day.

From 10 A.M. to 12, the assembled class, dividing into three portions, each accompanied by one of the physicians, was occupied in going round the building, making observations for themselves, and more particularly on those patients to which their attention had been particularly directed in the open-

ing remarks. On their return a substantial luncheon was liberally provided in the Committee room of the Asylum. At 1 P.M. the class reassembled in the private apartments of the Governor, where Dr. Conolly delivered his lecture, and which was always concluded in time to enable the gentlemen to return by the 20 minutes past 2 P.M. train to Paddington.

The private nature of the course, its delivery *sine mercede*, and the hope that its details will ere long be communicated to the profession in an authentic shape by the pen of its able and accomplished author, restrain the writer of this notice from alluding to more than the topics of the lectures; but he cannot forbear to record his thanks to the professional staff and authorities of the Asylum for their courtesy, and to express the pleasure which he felt, in common he believes with all present, in the interesting hours he spent at Hanwell.

The topics chosen by the lecturer were—An exposition of the principles and advantages of the system of non-restraint pursued in the Asylum; Mania in its recent and chronic form; Melancholia; Insanity combined with epilepsy; Puerperal insanity; General paralysis (a disease, Dr. C. remarked, that had not been met with except in connection with insanity, and which was first described by Messrs. Bayle and Calmeil, as observed by them at Charenton); general observations on the various forms of mental maladies; and one lecture on the principles which should regulate the construction and general management of lunatic asylums. Dr. Conolly, in conclusion, acknowledged and thanked the Governor and resident medical officers for their invariable kindness and attention, and for the constant desire they evinced to forward his views on this and every other occasion. He stated that he had left out nearly all points requiring lengthened discussion. He had said very little upon the morbid anatomy, because experience had made him less capable of connecting any particular form of insanity with any particular lesion than he had fancied himself capable of doing when he had not seen much practice, but had derived most of his knowledge from reading. There were, indeed, several forms of mental affection, such as incoherence and imbecility, comprehending a vast range of maladies, to which he had scarcely alluded; while dementia, a state resembling idiotcy, but differing from it in not being congenital, he had not touched upon—indeed, the subject of insanity was so vast, that "the general treatment affected almost the whole range of human action, and the whole sphere of human occurrences."

The night before the concluding lecture, an attempt at suicide within the Asylum led

to some clinical remarks which contain many useful cautions, and will serve to lay before your readers as an excellent specimen of the valuable instruction afforded by the lessons of Dr. Conolly.

This attempt, he observed, arose from a defect in the arrangements, by which the ward was left for a short time without an attendant—the effect of an order given by non-medical authority. Each ward has two attendants; but one being ill, the other was obliged to leave the ward, because it was contrary to regulations for her dinner to be brought into the gallery. In her absence a quarrel arose, and one patient getting into an ill humour, the disposition to suicide became so roused, that she evinced the strongest determination to destroy herself; and the consequence was, that the whole establishment had been kept in a state of disturbance and anxiety the whole night. The usual means were resorted to: removal to a padded room—the administration of a shower-bath—a strong dress put on, and an extra night attendant appointed. She was soothed by kindness, watching, and care, so much, that during the visit this morning she was found helping to clean the ward.

Alluding to this case during the lecture, Dr. Conolly remarked, that nothing could be more irrational than to suppose that insane patients can take care of each other. The regulations of an asylum should invariably provide for the presence of an attendant in every room. The entire executive of an asylum should always centre in one person, who should be held responsible for all the good or evil done within it. Divided authority often led to a contention for supremacy, or, at any rate, the government was defective, in consequence of persons giving particular orders, which were incompatible with the general scheme of management. In this instance the order regulating the dinner had rendered the more important object of the medical advisers, of never leaving the ward without the presence of one attendant, impossible. The consequence had been a quarrel among the patients; a suicidal one had been put into a bad humour, the whole of the patients in the ward seriously disturbed, and all the officers of the establishment placed in a state of great anxiety during the whole night. It is indeed, continued the Doctor, usually owing to the neglect of these little points that the most serious accidents occur, and produce blame to the system of non-restraint, and to the attendants, for what they themselves are rendered incapable of preventing.

At the conclusion, an address, expressive of the thanks and esteem of the class, was drawn up by the pupils, signed by every gentleman present, and acknowledged by Dr. Conolly in suitable terms.

MESMERIC SKILL IN ESCAPING FROM DIFFICULTIES.

"I FEAR I am in for it, touching my compass expenses!" M. Thilorier's experiment of magnetizing the key by the influence of his will, has not succeeded in presence of M. Arago. True, indeed, M. Thilorier pretends that he was *neutralized* by the illustrious perpetual secretary, and having less fear, as it seems, of the neutralizing powers of M. Dutrochet, he requested permission to repeat the trial in the presence of that gentleman, who at once consented. I am not yet informed of the result. It will be matter of much regret if so brilliant a discovery be not confirmed. All the priests and all the priestesses of the magnetic faith have been in commotion upon the great news. So, they have said, magnetism again is introduced to the Academy, which despised it! There are some, however, who maintain that the story of turning a bar of iron into a magnet is but an artful ruse to lead the attention of the savants of the Academy to the consideration of other phenomena that are not less surprising. And it is unquestionable that Messrs. the magnetizers are extremely adroit, and that they extricate themselves from the most difficult situations with marvellous dexterity. Let me give you a proof of the fact.

A friend of my own, very sceptical, was one evening at a party where a somnambulist was performing prodigies; and, pressed by the mistress of the house to address a few questions to the performer, he led him to a small house among the Pyrenees, which he requested him to describe. The somnambulist desired a few additional passes of his magnetism, and commenced his description, which, as it happened, whether from accident or otherwise [one small house in the Pyrenees, for example, being very like another,] was really pretty correct.

"Sir," said my friend, "you are extremely *lucid* this evening, and I beg you to inform me further what my father has been about to day?"

"I see your father at a great distance from this," said the seer; and then he went on to narrate, from hour to hour, what the old gentleman had done during the day; entering into the most minute particulars. "And now, to conclude, he is laid comfortably in a bed of such and such a fashion."

The whole party listened with avidity, and looked into the eyes of my friend to learn whether or not the somnambulist had spoken correctly. My friend turned to the magnetizer, and said:—"There is only one slight anachronism in the tale of your somnambulist—my father has been dead these twenty years."

"Sir," replied the magnetizer, taking him

by the arm, "your objection is worthless: *no one is ever sure of knowing his father!*"

You will guess the burst that immediately took place among the company. My friend, it must be confessed, cut a pitiful figure, and literally found nothing for it but to beat a retreat at the earliest possible moment.—*J. Raimond, in Gazette des Hépitaux,*

QUARTERLY TABLE OF MORTALITY.

THE deaths registered in the last quarter (ending June 30) amounted to 38,925, which is less by 7116 than the deaths in the previous quarter, and 1283 less than the average of the corresponding spring quarter in the five years 1838-42. Allowing for the increase of the town population, the mortality was ten per cent. below the average of the season.

The reduction in the mortality has been unequally distributed over the kingdom; but it has been most remarkable in the large manufacturing districts. Small-pox and scarlatina have been epidemic in the metropolis and elsewhere. The deaths in the quarter from small-pox were 425. The epidemics most frequently mentioned in the country districts are scarlatina, measles, small-pox, hooping cough, and typhus.

MORTALITY OF THE METROPOLIS.

Deaths from all causes registered in the week ending Saturday, July 27.

Dropsy, Cancer, Diseases of Uncertain Seat	108
Diseases of the Brain, Nerves, and Senses	287
Diseases of Lungs and Organs of Respiration	225
Diseases of the Heart and Blood-vessels	30
Diseases of Stomach, Organs of Digestion, &c.	107
Diseases of the Kidneys, &c.	8
Childbed	6
Paramenia	6
Ovarian Dropsy	1
Disease of Uterus, &c.	3
Arthritis	2
Rheumatism	2
Diseases of Joints, &c.	2
Carbuncle	2
Phlegmon	6
Ulcer	0
Fistula	0
Diseases of Skin, &c.	0
Old Age or Natural Decay	53
Deaths by Violence, Privation, &c.	23
Small Pox	49
Measles	23
Scarlatina	83
Hooping Cough	18
Croup	6
Thrush	15
Diarrhoea	43
Dysentery	6
Cholera	6
Infuenza	1
Ague	0
Remittent Fever	1
Typhus	37
Erysipelas	1
Syphilis	0
Hydrophobia	0
Causes not specified	2
Deaths from all Causes	1608

Medicine and the Collateral Sciences.

FRIDAY, AUGUST 16, 1844.

ON
MILITARY HYGIENE,
AND PARTICULARLY UPON
THE CLOTHING OF SOLDIERS.

By FREDERICK ROBERTS, Esq.
Assistant-Surgeon 59th Reg.
[Concluded from p. 517.]

(For the London Medical Gazette.)

THE infantry cap, lately introduced, I regard as a great improvement on the old one, and it cannot, I think, be altered for the better. It is made of felt, with leather on the top; it has a large horizontal peak in front, and a smaller one behind inclined downwards, which protects the back of the head from the sun and cold, and does not appear to lead the rain within the collar down the back, as some assert; the peak before saves the face. The shape of the cap is a truncated cone, and in front is ornamented by a brass plate, surmounted by a round light tuft. It is light, and fits the head well, by reason of the conical shape adapting itself better to, and over a larger surface round the head, in reverse of the old cap, which had a perpendicular peak, was an inverted, truncated cone—so contracted at the base as to permit only a *cord-like* extent of it coming in contact with the head to prevent its falling down over the face. The present cap combines usefulness and ornament sufficient for the general purposes of the infantry soldier; who, however, would certainly in the tropics be more comfortable with a straw hat, could he be so indulged. In North America he wears a cap suited to the country, made of fur. The forage cap is made of thick blue worsted, with the crown broader than the base, has a light tuft on the top, and is without a peak—permitting the man's eyes to be exposed to the rays of the sun and glare of light, as well as to a greater share of wind and dust, than the black,

or full dress, cap. As ophthalmia rages in countries where the turban and fez cap are worn, and prevails very much in the army, not in any one colony in particular, but very generally, it would appear that want of protection from the rays of the sun, from dust and wind, in the absence of a peak to the head dress, may in some measure account for the frequency of the disease, and suggest the propriety of altering the fashion by adopting the peak. It would be deviating very much from martial notions to recommend a low-crowned hat like the Swiss in the service of the Pope, although this hat has very superior advantages.

The black leather stock, worn by the soldier, must prevent that freedom of action about the neck necessary to free respiration; and its constriction, further increased by the tight collar of the coat, is injurious to the jugular veins, by the pressure exerted upon them at the base of the neck impeding the return of blood from the head. If made of softer leather, or of horse-hair, it would, I think, answer all purposes; such as keeping the man's head up, especially if the collar of his coat was straight, and not aloped off from the base upwards, which would expose this more flexible but more salubrious stock.

The coat of the infantry soldier of the line is made of red cloth, of thick but not compact texture. The collar is made to fit close to the neck, and is cut away from the base upwards, and bound to the neck by a hook and eye. It is single-breasted, and buttoned from the throat down, fitting closely to the body; the flaps behind are not so large as those of a civilian's coat. In England, and in cold countries, it is lined and somewhat padded. The single hook to the coat at the throat, and cut-away collar, conduce to occasion more strictures about the neck than when the collar is straight up, and confined by three hooks, which spread the pressure over a greater breadth, and relieve the man from much tightness in one place,

like a cord. The straight collar is worn by the artillery and cavalry.

Double-breasted frock coats, like those worn, I believe, by the Austrian infantry at present, appear to be more adapted, and more certain to ensure a continued thermal comfort to the soldier at home and in many colonies, than the present coat, which, further, is of course much too tight to permit sufficient freedom of play to the muscles of the neck, trunk, and upper extremities, and to favour easy respiration and healthy action in the skin. This coat is worn on guard at home and abroad, at many of the commanding officer's parades, and on Sundays, besides some other occasions.

The soldier's shell jacket is made of the same materials as his coat, but it is not lined, on account, probably, of the expense it would entail upon the soldier, who pays for the alteration of his clothing. This is the jacket generally worn by the soldier, both in and out of barracks. In-doors, and very generally in the barrack square, it is worn open, and exposes the chest, which is protected only by the shirt. It is single-breasted, and hooked, like the coat, at the collar, except in some few corps, and in the cavalry and artillery. It fits close to the body, and scarcely descends to the hips, except in those regiments where smartness in dress is of secondary regard. The alterations for the better in this article of clothing would be to line it, and make the collar straight, as in the cavalry and artillerymen's dress, so as to obviate, in a measure, its stricture about the neck.

The soldier at home, and in many of the colonies, wears thick cloth trousers, of the same texture as the cloth of his coat, in winter; and in summer white linen. For fatigue and night works in the West Indies he is served with a pair of blue serge; and in India, with the same, or blue cotton or linen trousers. The texture of the soldier's cloth should be improved to afford greater warmth. In the cavalry and artillery the men wear better cloth than in the infantry. The black, or as it is called, I believe, grey cloth of the infantry soldier's trousers, is of loose and perishable texture. Its colour is liable to change to brown, and is dyed by the men with solution of copperas and log-wood; often, I believe, just before parade, &c., a process which cannot be conducive to health. The black trowser is worn in winter, in wet weather at other seasons, and in both summer and winter on night duties.

The white linen trousers, worn in summer at home, and throughout the year in many colonies, should be abolished, as quite insufficient to afford that thermal comfort necessary, in an essential degree, to the soldier on the inactive duties on guard, many spiritless drills, and the monotonous

occupations of the barrack room; though the men do wear, occasionally, the black trousers on fatigue, and in the barrack room. Exclusive of the linen being inadequate to afford sufficient warmth, its wear is attended with more evil than virtually can be assigned to the article itself, but which, of necessity, must often occur. The knapsack is made only to carry a certain number of articles, and the number of white trousers allowed is two. These are washed once a week, and one pair is supposed to last clean three and a half days; but as this is evidently not practicable, recourse is had, before parade and at other times, to sundry spongings and partial washings of the said article of white linen, which is oftener wet than dry when again put on, as in cold wet days in summer it does not admit of being dried, and fire is seldom lighted in the barrack-room at this season, even supposing it were allowable to dry it there. The knee-cap, in particular, soils the white trousers, which, before next parade, *must* be clean; and this recleansing is only effected by the above process.

Pipe-claying is, of course, only another mode of washing, and is a process which, when the army wore white flannel jackets, was supposed to have been productive of much sickness, and the jackets were upon that supposition, I believe, discontinued.

It is scarcely necessary to remark that white trousers are worn in civil life only as articles of luxury, and by those whose wardrobes permit of a change on the slightest emergency—a matter impossible to the soldier. Even in the warmest climates I think it not only unnecessary for the soldier to wear white linen trousers, but I do not think he can do so with impunity; taking his habits and mode of occupation into consideration, the idea often entertained about the effect of white trousers in hardening the men is very dangerous, and void of reason.

The soldier wears worsted socks and strong linen shirts, both which articles, provided they are kept in repair, demand no alteration; although in hot climates calico would certainly be preferable, as in cold countries it is both warmer and cheaper.

The infantry of the line wear Blucher boots, which are, perhaps, better, and attended with less trouble, than shoes and gaiters. The only fault noticeable is that the heel is occasionally too high, and entails greater labour upon the man in marching.

The great coat is made of grey cloth of loose texture, and is so light as to weigh, on the average, when new, but five pounds. It is rather more capacious than a civilian's coat, and is so fashioned in order chiefly to go over the man's pouch. The collar is upright and loose. It is buttoned by a single

row of metal buttons, and is altogether a sorry material to issue only triennially, inasmuch as the wear and tear reduces it, on the average, to a worthless quality long before the expiration of the period assigned for a fresh issue. It has a cape, and it is slightly lined at the upper part. Its perishable nature requires serious consideration.

Soldiers do not possess that physical perfection of person which can warrant the adoption of a universal standard in their clothing. Individuals differ from each other so widely in their external conformation, that it seems little less than absurd to establish a rule of quantity and measure in regard to clothing. Every one knows, however, that the clothing of the army is manufactured by mathematical calculation. Men of five feet seven inches have coats and trousers of a certain width, length, &c. The scale of measurement comprehends six sizes. The clothes, thus made upon abstract principles, are, however, often altered to fit the men better, when sent to their respective corps. The abstract principle is nevertheless preserved in the army. A man with a spare frame and delicate constitution is clothed in the same manner as he with the athletic frame and sound constitution. Again, a man with a chronic cough, difficulty of breathing, palpitation, &c. has his coat made as tight as he who can bear it so with comparative impunity.

The dress of the soldier is generally unfavourable to muscular action. In addition to this, the nature of the duties of a soldier does not admit of much variety in muscular action; and the same want of varied motion which is the cause of muscular weakness is still further aggravated by the tight pressure of the coat, straps, and belts, interrupting the play of the muscles. During the formal walking up and down on sentry, the legs only are called into activity. Without noticing the injury going on in the organs of respiration and circulation from the same and other causes, debility of the body, and diminished tone of all the animal and vital functions, are the consequences. On the other hand, excess of exercise is often no less an injury to the soldier. On field-days, at punishment drill and on march, when he carries his pack, several rounds of ammunition, fire-lock, and belts, he is put to very violent exercise, and diseases of the heart and large vessels are the consequence.

That specific deteriorating influences in the life of a soldier exist, and that the tendency of these influences is to produce organic diseases, more than other external causes, cannot, I think, be doubted*. These

predominant influences are conspicuously observable in a particular corps, whose circumstances are but little altered, and who are not exposed to a superior cause (so to speak) of disease.

It is in the Foot-Guards that this power is most ascendant, and where, in the absence of epidemic and endemic influence, the tyrant prevails and usurps complete dominion, and suffers no other power to appear. This body of men is not exposed to the causes which produce fevers and dysenteries, which are the chief causes of mortality in the tropics and elsewhere. It is, however, nearly as much exposed as the community at large to the diseases of this country, from which it suffers nearly in the same proportion; but the men composing it mostly die from the diseases produced by influences which predominate with them: at the corresponding rate soldiers of the line die from yellow fever, or other diseases of epidemic or endemic type, when exposed to the causes thereof. The same influence is again seen in the case of the black troops in the West Indies, where the white troops are more under the power of epidemic and endemic diseases, by reason of the climate not being so congenial to their constitutions as to those of the natives of the tropics. The black troops suffer much from diseases of the chest, from the causes thereof in soldiering (to use a familiar military term) predominating over those of fevers and dysenteries, to which they do not yield so soon as to the influence which military life exerts upon their frames. Although the Foot-Guards wear waistcoats of red cloth, and are so far better protected than the line, it is no argument that good clothing does not protect men from consumption, when we know that these troops die much oftener from that disease than those of the line. The duties of the Foot-Guards are always the same, allowing on the average three nights a week in bed; whereas those of troops of the line are often much lighter, both in large and small garrisons. In the latter, where a barrack-guard only is required, the men are often for a week or more in bed every night—a circumstance of material consideration, when the tight clothing, interrupted sleep on hard boards, &c. are taken into account. Again, soldiers of the Foot-Guards die from the gradual deteriorating influence of a military life, which is seen to produce debility, premature senility, and to develope phthisis; when, on the other hand, the soldiers of the line die from the same cause more or less, but greatly also from diseases of epidemic and endemic character, and before the deteriorating influence which affects the Foot-Guards has had time to complete its work; though this deteriorating power places them in a much less favourable state to recover from disease of any kind than they

* It must be understood that it is from their *degree* and *kind* that these influences are termed *specific*.

would be, were they differently situated. I conceive the comparatively little exercise taken by the soldier in general, the impurity of the air of his habitation, and often the deficiency of light in it, sufficiently powerful to produce the great extent of consumption that prevails in the army, when taken in conjunction with the faults in dress.

The circumstances under which I believe the present mode of dress of soldiers to act most destructively are when the men are already labouring under organic disease; and once organic derangement is established, I consider them to be of all others the most difficult afterwards to protect from a recurrence of attacks, and from extension of disease. A man with pleuritic adhesions, deposition of tubercles at the apices of the lungs, or with thickening of the mucous membrane of the bronchial tubes, encased in tight uniform, with cross belts and knapsack, must suffer from want of due expansion of the chest; the respirations must make up in rapidity and frequency what the lungs want in capacity. The respiration becomes *puerile*, and tubercles are quickly deposited, or, if already present, their rapid softening follows.

"The anatomy and functions of the skin have been made the subject of much research by modern physiologists, who have demonstrated that it has a very important part to perform, both in the animal and vegetable kingdom, that it is a powerful auxiliary to the lungs in oxygenising and in vivifying the blood, and an extensive cunctorium by which the fluid materials that have performed their duty in the economy are eliminated. The importance of its being kept continually in a clean and perfectly free state, in order that it may be able to perform these various functions, has been vividly felt by scientific writers, and has been equally vividly expressed by them."

The condition of the soldier is such, although he practises certain evolutions in the course of the day and week, as to be unfavourable to due performance of the functions of the skin. It is familiar to all that retention of clothes on the person for a long time favours the accumulation of dirt thereon. The cause of this is, probably, the want of proper circulation of air round the body to promote the evaporation and dissipation of the cutaneous secretions. On guard, the soldier retains his clothes for two days and one night, with little variation. When confined in the guard-room for misconduct, he remains without change for periods varying from twenty-four to seventy-two hours, and probably longer. Indeed, when waiting a court-martial, he is often a week there. The most superficial observer cannot have failed to remark how soon dirt accumulates upon the person of the soldier, whose close-

fitting dress prevents the contact of air about his body, and, with what has been advanced above, conduces to irregularity in the function of perspiration. The condition of things termed "checked perspiration," said to be produced chiefly by sudden transition from heat to cold, &c. is much favoured in the alternations of violent exercise and passive inaction at drill, and on sentry, especially in cold weather. To suppress evaporation, or the physical process of perspiration, extreme humidity, and a high external temperature, are essential; and this condition of atmosphere is found in the sciroc wind in the Mediterranean, and in the torrid zone, where the quantity of vapour contained in the air is much nearer the point of saturation than in the temperate zones, and in consequence of which evaporation is much less than might be supposed from the high temperature. By virtue of this state of atmosphere, again, there is an increase in the perspiration by transudation, which depends upon causes inherent in the living economy, but which may be modified by external agents. Supposing, further, the relative temperatures of the air and of our bodies to be such as to prevent evaporation, there is still here a state of things unfavourable to the healthy condition of the body. According as the sweat becomes abundant, it spreads over the body and forms an external layer, which, intercepting the contact of air with the skin, prevents transpiration immediately from the body. That derangement in the function of perspiration by the influence of physical agents is favoured by exposure to relative cold and moisture on sentry, during inspection of the men on parades, even during the course of a drill, when not active, and likewise at night, especially during sleep, when the power of regenerating heat is least strong, must be obvious to all.

Having attempted to show the ill effects of defective clothing upon the soldier's frame, and how little less hurtful it is when wrongly made, I have now, besides what I have suggested should be altered in the articles of dress already in his possession, to propose that the Infantry soldier should be supplied with further articles of clothing. To this I know strong objections will be raised, and amongst others will be the want of capacity of the knapsack (already too weighty) to contain them. It is not the general custom for the Infantry of the line to wear waistcoats and drawers of any material. By the clothing-warrant, the Light Dragoons and Cape-Mounted Riflemen only are ordered to be supplied with flannels; but it is the custom with the Cavalry generally to wear the same, and, indeed, even drawers. In a former part of these observations I expressed a doubt as to the troops at the Cape wearing flannel; the clothing-warrant orders the

native corps to wear it, and I have since learned that it is a very general habit among the Infantry to adopt the custom of the colony. In the Infantry throughout the army, it is also more or less worn, either by will or by recommendation of the medical officers.

The proportion, however, wearing waistcoats and drawers is small, and even this proportion is not invariable in their *constant* use—many throwing them off in summer, and others failing to re-supply themselves when necessary. As these articles are worn by some, it is reasonable to believe that with little deviation in the disposition of the soldier's kit he might easily be always in possession of a waistcoat and a pair of drawers, or two waistcoats. I have heard that a regiment, lately arrived from Canada, had in use flannel shirts in the West Indies. This approaches to what I should wish to see adopted, but falls short of many desirable emendations in the physical and material relations of soldiers. Better, then, to fulfil what physiology and the anatomical structure of the frame indicates, under circumstances of the great perversion in the dictates of nature which obtain in the life of a soldier. I think he should be supplied with additional clothing, according as the nature of climate and duty varies, and that the alterations already proposed, or such others as meet the principles implied, should be submitted to experiment. When the circumstances under which the influence of dress falls shall be modified, the causes of disease will also be so far removed.—A man will suffer less by remaining in the same clothes for twelve than twenty-four hours; by continuing in a tight dress under arms for an hour than for three hours; or when exposed to cold on sentry, or elsewhere, for an hour, or half an hour, than if he was so exposed for two hours. It is presumed that the soldier's clothing will undergo a change sooner than these circumstances; which, however, are not at all uncontrollable. Though, doubtless, very imperfectly demonstrated, it is supposed nevertheless to be not too much to infer from the foregoing remarks, that were the soldier's clothing more abundant and less opposed to the requirements of nature, did it afford greater freedom of action to the functions of respiration, perspiration, and muscular motion, he might better be preserved from the calamities to which his mode of life exposes him at present; that if experiments were made in his favour upon the principles inculcated, it might be a step towards lessening the power of the destructive influences inseparable from his condition.

ON THE
PATHOLOGY AND TREATMENT OF
OVARIAN DISEASES;

WITH CASES.

By DR. SAMUEL J. JEAFFRESON,

Physician to the Chelsea, Brompton, and Belgrave Dispensary, &c.

[Continued from p. 590.]

CASE VI.—*Two ovarian tumors, combined with ascites—disease of the stomach—supposed pregnancy.—Death within a year of the first symptoms of the disease.—Autopsy.*

I was sent for to see Mrs. A., who was under 30 years of age, in consultation with Mr. Eaton, on the 24th April, 1839.

The patient considered herself eight months pregnant; the breasts had enlarged and secreted milk. "Up to within the last four or five weeks she had been conscious of the movements of the child, which suddenly ceased, and then the breasts became flaccid." She suffered considerable inconvenience and dyspnoea from the bulkiness of the abdomen. She rather expected, from the sudden cessation of the movements of the child, and subsidence of the breasts, that all was not right, and that the child was dead. A few days previously to my visit, she sent for Mr. Eaton, in consequence of feeling, as she supposed, incipient labour pains. She was the mother of two living children. We now found the abdomen enormously and uniformly enlarged, and distended by fluid; fluctuation being perfectly distinct in all directions. As she lay on the back, the upper part of the abdomen around the umbilicus was resonant on percussion, and the sides low down perfectly dull. The tension of the abdomen was so great that we could not ascertain anything like the gravid uterus; but something like a tumor was perceived in the left iliac region. The bowels had not acted for ten days. The pulse was feeble, and the tongue white and furred. There was no anasarca. The patient was very feeble and low, and the countenance expressive of much anxiety.

She had laboured under an abscess for several months in the neighbourhood of the left crista ilei, which had discharged very considerably, and healed about the period, as she supposed, of her falling pregnant. The diagnosis

which we formed was that she was labouring under ascites, that pregnancy had not existed, and that the tumor felt in the left iliac region was ovarian. The treatment, in the first instance, was chiefly directed to the state of the bowels. Brisk purgatives were administered, and followed by enemata of rue and colocynth.

Considerable temporary relief was afforded by this treatment. The abdomen was rendered less tense, and the tumor in the left iliac region was felt more distinctly. This relief was, however, of but short duration; the fluid in the abdomen rapidly increased, and induced such embarrassment of the respiration, &c. as to render the operation of paracentesis necessary in the course of a month or five weeks. The operation afforded great relief to her more urgent sufferings, so much so that although she became gradually so much lower as to appear in imminent danger, she earnestly begged for its repetition only three weeks afterwards, when there seemed some risk that she could hardly survive the operation itself. On both occasions the quantity of fluid evacuated by paracentesis was very considerable, and was, throughout the whole period in which it flowed, clear and limpid. She survived the second operation about a week, and sank on the 17th June, about two months from the period of my first visit, and four weeks from the first performance of the operation of paracentesis.

Post-mortem examination, 18th June, 14 or 16 hours after death.

Body extremely emaciated, and the abdomen so attenuated that the bowel was cut into even by the first slight incision of the abdominal walls. The abdomen contained a good deal of fluid. The peritoneum appeared thickened and opaque. On attempting to remove the abdominal viscera, a considerable indurated growth was found to occupy the greater curvature and part of the body of the stomach, but not, however, involving its valves. On dividing this substance, it was found to be of the hardness of ordinary scirrhus tumors, but less radiated and fibrous in texture, and more resembling, in every respect, the hard portions of ovarian tumors. By its size, hardness, and the adhesions which had been contracted, I suspect this tumor must have pressed upon the

vena porta, and so have contributed much to the ascites. The liver was rather smaller than natural, and not otherwise diseased.

The peritoneal covering of the small intestines presented several spots of puckered up serous membrane, exactly as if there had been an ulcer nearly or entirely penetrating through all the coats of the bowels; on opening this, however, the interior portion corresponding to the supposed cicatrix was found to be occupied by an elevation, of corresponding size, of a hardened matter in all respects resembling the disease in the stomach.

The tumor in the left iliac region proved to be the ovary of that side, in size about twice as large as the closed fist; the right ovary, exactly similar in size, &c. was jammed down into the pelvis, and there attached by adhesions to various parts. The fallopian tubes and their imbricated extremities were rather thickened and puckered, and seemed to be taking on a similar form of disease to the ovaries. The uterus natural in size, of a dirtyish white colour and firm texture. The section of each ovary afforded evidence of a similar construction. The central portion was hard and white, and intersected by bands of fibres radiating towards the circumference. Each tumor appeared composed of various well-defined cysts or compartments, some hard and perfectly white, and non-vascular; others slightly softer and highly vascular; others much softer and running into a state not unlike the curdy contents of scrofulous glandular abscess; others of a semi-transparent gelatinous consistency; and others again so fluid as readily to flow out when the cysts were punctured.

General Observations on the Pathology and Treatment of Ovarian Disease.

The preceding cases of ovarian disease might easily have been multiplied by reference to my own note-book, or the publications of other authors on the subject; they will, however, answer the purpose of illustrating some general observations on the subject.

Pathology of Ovarian Disease.—Ovarian tumors, as it appears, may be entirely fluid, or partially solid and fluid in various proportions. Are the two forms of disease identical in their origin?

Much difficulty necessarily involves the subject of the early formation of ovarian tumors; for whilst it is all but impossible to pronounce what might have been the result in the cases of some of the more trivial alterations in the structure of the ovaries which have been casually observed in post-mortem examinations, without the existence of any symptoms during life to have directed our attention to those organs, it is equally difficult on the other hand, from the examination of these parts when affected by long-continued disease, to deduce what were the exact conditions of the parts in the incipient stage of such affections. In the examination of ovaries in cases in which no disease of these organs was suspected during life, it is not uncommon to observe a small cyst or vesicle beneath their peritoneal coat, and situated in the structure of this organ itself; such cysts or vesicles vary in size from that of half a horse-bean upwards, and usually contain, at least so far as I have observed them, a perfectly clear, transparent, semi-gelatinous fluid. When the cyst is very small, the remaining portion of the ovary does not necessarily present any structural alterations. Are these cysts the earlier stages of ovarian dropsy? The general opinion is, I believe, in favour of this supposition. The fluid in this case probably occupies one or more of the cells of the Graafian vesicles, and that this may be the earlier stage of ovarian dropsy in some instances is probably correct; but I must confess my own unwillingness to regard it as the sole, or even as the frequent primary condition which leads to the establishment of this form of disease.

Firstly, observing the thinness of the walls of these cysts even at an early stage, it is difficult to imagine how they should become so stretched and attenuated as to contain many quarts of fluid without giving way and bursting into the abdomen; and secondly, it is no easy matter to conceive how they should be able to afford so prodigious an amount of secretion. With respect to the former supposition it should not be forgotten that the distended ovary is at large in the abdomen, and receives no support from surrounding parts; if the tunica vaginalis testis may be very greatly distended with fluid without sustaining any rupture, it should be

borne in mind that this membrane is uniformly surrounded by other parts which afford it support in all directions. If this condition ever constitutes the first stage of ovarian dropsy, I suspect it is of those cases in which the dropsy is contained in one single cyst only from the first—the unilocular form.

Whether ovarian tumors of any considerable size have ever been observed to be uniformly solid, I am not aware; no such cases have come at least under my own personal observation; by far the most common form of the affection is that in which the tumor is partially fluid. Cases IV. and VI. afford examples of this form of disease; the peculiar structural appearances of which are more particularly detailed in Case VI. Whether such cases commence from the very first in this mixed form or not, it is not easy to decide; in some instances, probably, they do; but I am strongly inclined to believe that the more solid parts undergo a gradual process of softening, and even liquification; the earliest stage of which commences in extreme vascularity, not to say inflammation. That this process of change actually takes place, seems to be established by the post-mortem observations made in Case VI. (of which I have seen numerous similar instances); it also seems further borne out by Case IV., both by the post-mortem observations then made, and by the fact observed during life that the tumors appeared to be becoming less universally hard; and still more so by Case V., in which a tumor apparently in the first instance as hard as stone, rapidly increases with symptoms of inflammatory character, and goes on to perfect softening, and the most complete cure by spontaneous rupture.

With respect to the essential character of the material, whether solid or fluid, which constitutes ovarian tumors, I am not aware whether they have ever been subjected to accurate chemical analysis or not; and it is highly questionable whether such analysis would lead to any improvement or increased certainty in the treatment of these affections; such, at least, has not been the case of other encysted tumors, whether fluid or solid.

The fluid contents of the ovarian cysts is in all cases that I have observed highly albuminous, and may vary

in its colour and consistency from a dark grumous appearance resembling coffee grounds, and from a ropy consistency, to a pale clear transparent fluid much resembling ordinary serum. The fluid may be mixed with flakes of more solid matter, impeding the flow of liquid through the trochar in the operation of tapping. It is also remarkable that the colour and appearance of the fluid vary at different periods in the same case. Instances are recorded in which a first paracentesis has brought away a clear, the second a turbid, and the third a clear fluid, and so on, and that, too, even when there could be little doubt but that the same cyst was punctured at each operation.

The more solid portions of ovarian tumors present no less variety in appearance; the whole or parts of the tumor may be as hard as cartilage, or of brain-like consistency. The differences of colour, consistency, &c. of the solid tumors, are chiefly due, I suspect, to different degrees of vascularity, and to different stages of certain natural processes of softening to which they tend in the majority of instances, when life is sufficiently prolonged to afford the opportunities for the establishment of such changes. In the more hard and solid portions of the tumor, the fibrous and radiated character which they assume has been already noticed in the relation of Case VI. To judge from the early history of the origin and the progress of the case to its ultimate termination, is another matter; but for myself, at least, I must confess, that were a small portion of some of the harder forms of ovarian tumor presented to me side by side with a similar portion of a scirrhus or carcinomatous tumor of the breast, I should be much puzzled to say which was which—to assign to the one, in fact, the characters of malignant, to the other that of non-malignant disease.

In all the forms of ovarian disease the cysts have been occasionally found to contain hair, teeth, bones, and other organized structures of this kind; it is, however, somewhat remarkable that these structures, said generally to be fetal rudiments, consist most frequently of the very parts which are last to be found in fetal life, and the absence of which, except in a very rudimentary state, is observed even at birth itself.

Symptoms and progress of ovarian

disease.—In many instances, during their earliest stage, these forms of ovarian disease afford no symptoms, none at least of sufficient moment or stability to call forth the attention of the sufferer, or to confirm the accurate diagnosis of the medical attendant; in fact, unless called in for other affections, no medical attendant will as yet have been applied to. The principal symptoms, indeed, of ovarian disease in all its stages, are due to its mechanical inconvenience. Before the tumor rises above the pelvis it is liable to induce inconvenience by pressure on the rectum and neck of the bladder, occasioning difficulty in evacuating their contents, and much pain: instances of this fact are found in Cases II. and IV. If one ovary only be affected the catamenia may continue regular; not so, however, when both ovaries are diseased. Dr. Seymour was, I believe, the first to draw attention to these facts, which are exemplified in Cases IV. and VI. At what period, however, of disease the catamenial function ceases, it is, perhaps, impossible to ascertain; probably not until the whole organ is involved in structural change.

The period of life at which ovarian disease is first established is almost invariably that between the first establishment and cessation of the catamenia. Most practical authors are disposed to consider its occurrence to be more frequent during the latter period of this stage of life than the earlier; that is, supposing on the average the catamenia to commence at 17, and to cease at 47, ovarian disease is more prevalent between the ages of 37 and 47, than between 17 and 37. May this circumstance be due to the fact that the ovary may become diseased in early life, but from accidental circumstances favouring its non-increase of bulk, may remain stationary for many years until some other conditions of the part or system may call it into more active growth, and thus give rise not in reality to its origin, but to its manifestation? That such may be the case does not appear impossible, judging either from the nature of the local affection itself, or from analogy with other forms of disease. Tumors which have remained stationary for many years have often been found suddenly to take on a rapid growth, and even a character of malignancy, which it is difficult to suppose

that they at first possessed. It is not always easy to investigate all the circumstances in life connected with the peculiar functions of the female organs of generation. Independently of the natural and healthy exercise of these functions, there can be no doubt that moral causes exercise a peculiar influence over them; and it is not always practicable to obtain information on the one point or the other. In Case V. it is remarkable that marriage did not take place till late in life—many years past the period which nature has marked out for the first exercise of the generative organs; whilst the disease, whether previously existing in a dormant state or not, was at least first manifested within less than a twelve-month of this period. That some peculiar conditions of the ovaria exist in many cases very long before the manifest development of the disease, is rendered more probable by the fact—if it really be a fact, and I have frequently observed it—that the majority of married women in whom the disease has been witnessed have been barren. Such, indeed, was the case in three out of the four cases of married women narrated above.

Much difference of opinion exists on the subject of the predisposing causes of ovarian disease; that is, whether any particular habit of constitution recognisable to the medical practitioner renders the individual more liable than others to the establishment of this form of disease. So far as I am acquainted with medical literature, no very decisive evidence is to be gathered on this subject; but I must confess my own disposition to go with Dr. Copland, and others, who consider the scrofulous diathesis as decidedly predisponent. Such was clearly the case in Nos. IV. and VI.; in both which instances the disease was rapid in its growth and fatal in its termination (in Case VI. not certainly fatal of itself), and in which no especial exciting causes could be traced. In both these cases also there is little or no reason to suppose that the disease could have long existed in a dormant state before they were discovered by the patients and their medical attendants.

With regard to the exciting causes of ovarian disease, little more can be said than that the maturity of these organs favours the development of the disease; since it is almost unknown at

epochs prior or subsequent to this period. Dr. Copland says, in his Dictionary, that Frank saw the disease at 13, and Itard at 14 years of age, but does not inform us whether the menstrual functions had been established in these cases. He himself declares that he has never witnessed the affection before the age of puberty. Nor is this more than happens of other organs, active disease of which is most liable to appear during the periods of life at which their functions are most energetically called forth. By the same general rule too, it may be stated, that inflammation of the ovaries, in whatever cause originating, and all circumstances tending to exercise morbid influences over the menstrual functions, are liable to excite the various forms of ovarian disease. Excessive sexual indulgence may therefore be fairly supposed to rank high amongst the exciting causes; and yet I am not myself aware that the affection is more prevalent amongst that class of persons who would thus be rendered most liable to it. Of the two causes I should feel more disposed to regard the want than the excess of exercise of those organs as the most frequent exciting cause of the disease. Every organ is by nature endowed with its appropriate functions; the natural action of which is most conducive to maintaining its structural integrity. Now we are not to suppose an organ is never excited, never receives impressions of any kind, because it is never exercised. In the case of arrested catamenia, for instance, are we to suppose that the organs therewith connected constantly remain in a perfectly uniform condition, both as respects the distribution of blood and nervous influence, because the catamenia does not appear?

There may be a natural excitement calling forth natural effects, the healthy performance of the functions of a part; or there may be an unnatural excitement calling forth unnatural effects, *i.e.* not a healthy performance of the functions of a part; or, again, the part itself being previously out of order, the source of excitement, though natural, may not be able to induce a natural and healthy effect. This is true not of one but all organs of the body.

Now it has occurred to me to observe many cases of ovarian disease amongst females who have married rather late in life. The ovaries have not been

brought into healthy action until long after the period of life at which they were by nature intended to be so; and then, perhaps, the healthy stimulus has come too late, and, whilst the former unnatural repose has acted as predisposing the present natural action, has even acted as an exciting cause of disease. Now if this view of the subject be true, it leads to very important considerations, and that, too, not in connection with the prevention of ovarian affections only, but many others. Farther, should the former proposition be true—that, in spite of the excessive venereal excitement in which they indulge (a circumstance naturally predisponent to the disease), this class of females are not, on the whole, found to be more frequently afflicted by it than others—it becomes a curious and interesting question whether their comparative exemption from a disease to which this circumstance would render them liable does not originate in the early exercise of those functions, at the period in which they were by nature intended to be exercised—the good effects of a natural exercise of a function more than counterbalancing the abuse of its excess; excessive exertion of a function at a period when the organ is ripe for its exercise being less pernicious than no exertion at all.

When Dr. Copland says (see his Dictionary, article Dropsy, Encysted, of the Ovarium), when speaking of this disease, “it is not improbable that it is connected with an often excited, but an imperfectly gratified, sexual appetite; hence its frequency in females who are sterile,” &c. &c. I am quite disposed to agree with him where the source of excitement has been unnatural, which comes under the second general proposition laid down above; whilst I should be disposed to observe that the apparent induction, “hence its frequency in females who are sterile, &c.” is in reality another condition under which the disease occurs, and belongs, in fact, to the third general proposition. The females are sterile because the ovaries are already diseased in structure or function; the excitement applied is natural, the result is unnatural, and ends in promoting inflammation, or other structural changes, in organs already impaired in function or structure.

From these arguments, if true, we should deduce that a reasonably early

marriage, unless, perhaps, under peculiar circumstances of predisposition, is likely to ward off the disease; whilst late marriages are liable to induce it: and, least of all, could marriage be recommended at a late period of life, when the slightest supposition existed of the presence of any incipient disease of these organs.

[To be continued.]

ON THE TRANSFORMATION OF PUS CELLS INTO A MUCOUS OR FIBROUS TISSUE.

To the Editor of the Medical Gazette.

SIR,

I AM aware of the hostility which all innovators upon established opinions must be prepared to expect, and of the number of persons ready to contest a claim to new facts.

If I had been ignorant of this before the publication of my Researches, it would have been made evident by the tenor of the arguments hitherto urged against my conclusions. I am told, on the one hand, that what I call a *demonstration* is an idle theory, a wild speculation; and on the other, that *my facts* are slender and erroneous inferences—nay, it has been asserted that a select few only can rightly discern the value of a microscopical appearance. I admit, to some extent at least, the latter proposition; but I affirm that there is no extraordinary difficulty in estimating the appearances of an object viewed through a microscope, that will not be speedily removed when the observer has had sufficient experience to enable him to consider calmly, and to describe faithfully, what he sees. I feel, at least, that I have nothing to fear, but every thing to anticipate for my conclusions, from a more extended use of the microscope, and an increased facility in making observations.

The object of the present paper is to draw increased attention to an experiment related pp. 249 and 250 of the Second Series of my Researches, and made for the express purpose of testing some of my views. This experiment I have repeated in several ways, with the following novel results:—

EXP. I.—A large chronic abscess was opened, and a great quantity of pus

discharged. Some of the pus was received into a wine-glass; it had the white opaque appearance and the consistence of cream. Twelve drops of the pus were dropped into a watch-glass, and ten drops of Brandish's liquor potassæ were added to them; they were well stirred together with the point of a pen-knife, and in less than two minutes the mixture became nearly transparent, and so plastic, that I was able to suspend the whole mass (twelve drops of pus and ten drops of liquor potassæ) on the point of a needle. Twenty-five drops of pus were then similarly treated with ten drops of the alkali, and the whole of this was suspended on the bare point of the needle. Fifty drops of pus, and fifteen of liquor potassæ, were then tried, with the same result; and, lastly, I found that *seventy-five large drops of pus, and twenty drops of liquor potassæ* (taking a little longer time to mix them), *could all be suspended on the point of the needle*, for as long a time as I chose, leaving the watch-glass in which they had been mixed nearly as dry and as clean as before they were placed in it. If a few more drops of liquor potassæ be added than the proportions here mentioned, the mixture becomes quite transparent, and it may then be gently drawn out into strings or filaments two or three feet long.

Now what are the events accompanying or preceding this singular transformation, and what are the results? I have shewn in the first series of my Researches, that liquor potassæ causes pus cells to burst open and discharge their contents; and it is evident that, in this experiment, the plasticity of the resulting material arises from the rupture of the cells. The fluid element of pus, before this event, is limpid; that is, it has no plastic quality or tenacity whatever; it drops from one vessel into another like water; but when a majority of the cells have been ruptured, and their contents mingled with the previously existing fluid, then the whole becomes exceedingly plastic and coherent; it will no longer drop from one vessel into another, and it exhibits all the microscopical appearances of fibrous tissue or of mucus. The event, therefore, accompanying or preceding this transformation, is the rupture of the pus cells, and the result is a mucous or fibrous tissue. I do not under-

stand by the word *transformation*, as applied to cells, any transcendental conversion of one object into another, but that they are altered in appearance by a living growth, or by death; in character by peculiarity of situation; and that when they burst or become ruptured, and their contents mingled with the fluid in which they float, they form either a fibrous tissue, a plastic mucus, or a secretion.

EXP. 2.—Provide a tall glass jar, a tumbler glass will do, filled with clear water, and two long needles fitted with convenient handles. Mix a few drops of pus with an equal number of drops of liquor potassæ, stirring them well together; if several air bubbles are included in the plastic matter which results, so much the better. Let the mixed materials be now transferred to the water, and if air bubbles are entangled in it, it will float at the surface.

Now take the needles, push the plastic mass under the surface of the water, and on separating the needles with a little manipulation it may be spread out into a most delicate, thin, transparent, and highly elastic fibrous membrane, exactly resembling some of the thin transparent membranes of the embryo, except in the presence of blood-vessels, or the *structureless basement membrane* of Mr. Bowman. In this experiment the number of entire cells or pus globules incorporated with the free molecules and the fibres may be varied at pleasure by varying the quantity of liquor potassæ.

Here, then, we find that we may form not only a glassy mucus, or a fibrous tissue, but a highly elastic and transparent membrane from pus-cells, from dead and dying, or degenerated cells; what the active and the living can do is seen in the spontaneous formation of a fibrous tissue in buffy blood. But it may be objected that the liquor potassæ does more, in these experiments, than rupture the cells; I therefore allowed these tissues and membranes to macerate in water for several hours, and I found them not at all altered in character or appearance thereby: I then removed them from the water, and placed them on turmeric paper, and there was not the least indication of the presence of any alkali; moreover, the fibrous structure was rendered still more evident, and not destroyed by immersion in weak acetic acid. Again, it may

be said that what I here call an elastic membrane is nothing more than a film of plastic mucus; to which I reply, if so, then that is a *new fact*; and that mucous is a form of fibrous tissue. Fortunately, these experiments may be repeated, and all the most essential of the facts observed, without the microscope.

I now ask the author of the review in the *Lancet* of August 3d, and the candid and impartial reader, whether my conclusion "that it is the corpuscles, and not the blood-fluid, which administer to nutrition," is or is not "a wild speculation!" The former must, I think, speedily repent the hasty remarks and rash admissions he has made: if he really has looked for, and not seen, the colourless-blood-cells accumulating in the vessels of the frog's foot after immersion in tepid water, I can assure him that a perseverance in his labours will be amply rewarded by a merited success; that is, if he will follow the plain directions given. But if he has seen "distinct exudation follow the stoppage of the blood," without seeing any of the colourless cells, then I accept this fact in support of my conclusion that cells are never formed in or from the exuded fluid. I have no intention of entering upon any argument, or of discussing the merits of this review; it consists of nothing more than statements here and there picked out from my "Researches," and of bare assertions flourished off with an array of good names. Such things may at any time be done without much personal trouble to damp the ardour of pursuit for truth, or to check the progress of knowledge and improvement in every science. I ask those who feel an interest in the establishment of *principles* worthy the name of medical science, to treat pus cells first with liquor potassæ, and then with diluted acetic acid, and to study the physical and microscopical character of the result; to examine the details of the structure of the clear and of the opaque mucus and mucous cells from the nares and other mucous surfaces; to watch the fibrillation of the liquor sanguinis, and the changes which the cells experience; to observe the various and singular alterations produced in the red and colourless cells of blood drawn from an inflamed spot after the addition of a little water; the disposition of the various groups of

isolated molecules; and the formation and interlacement of the fibres; and to study the objects contained in the limpid and clouded fluids of cutaneous vesicles. I then ask them to examine the moving molecules in the interior of blood, saliva, and mucus, or tissue and pus cells, and to study the phenomena of the circulation in the irritated vessels of the living frog; I ask them to do these things before they dismiss my theory or rationale of nutrition as a "glaring instance" of error.

Finally, I would ask those who do not choose to trouble themselves with these *demonstrations*, to take no part in the discussion, for it is useless to urge against me only those views and opinions which I contend they show to be no longer tenable.

I remain, sir,

Yours very obediently,

WILLIAM ADDISON, F.L.S.

Great Malvern, Aug. 6th, 1844.

ON THE
PATHOLOGY AND TREATMENT
OF THE MORBUS BRIGHTII;
AND VARIOUS FORMS OF ANÆMIA.

By G. OWEN REES, M.D. F.R.S.

Fellow of the Royal College of Physicians; Physician to the Pentonville Prison; and Assistant-Physician to Guy's Hospital.

(For the *London Medical Gazette*.)

THE object of the present communication is to direct attention to certain diseased conditions of the blood. Before doing so, however, I must venture to premise, in relation to the structure of the blood corpuscle, that whatever may be the difference of opinion among micrographers, concerning the existence of a nucleus, and on the mode of genesis, the fact that these bodies are composed of a membranous sac enclosing colouring matter has been so completely proved by experiment, and is now so generally admitted, that I shall proceed by regarding it as fully established, and show how it explains many pathological conditions which cannot otherwise receive interpretation.

In the course of some observations on the state of the blood in disease, published in the *Guy's Hospital Reports* for April 1843, I directed attention to its extreme tenuity in certain stages of the morbus Brightii, and entered upon the consideration of that condition as con-

stituting the true cause of the deficient proportion of hæmatosine observed at later periods, and which acted by interrupting those endosmotic changes occurring between the contents of the corpuscle and the chyle, when each fluid possesses its ordinary specific gravity. Further experience has tended to confirm this pathological view, and I am anxious now to allude to certain other forms of disease in which a deficiency of hæmatosine is the leading characteristic, and consider how far such morbid states may be regarded as identical with albuminuria in their humoral relations. The increased quantity of water circulating in earlier stages of the morbus Brightii is no doubt caused by the discharge of albumen with the urine taking place as a constant symptom. Thus the liquor sanguinis is deprived of one of its most important constituents, and the watery condition induced will go on to the production of that secondary state in which the absence of hæmatosine from the blood becomes the leading feature of the disease. This change from the one state to the other is well shown by the following analysis made upon blood drawn from patients suffering under the morbus Brightii: the first at an early, the second at an advanced stage of the disorder.

	1.	2.	Health.
Water . .	805.71	853.11	792.20
Solid matters } of serum }	85.56	81.28	87.85
Fibrin and } corpuscles }	108.73	65.61	119.95

The decrease in the proportion of hæmatosine observed in persons who have lost large quantities of blood, and in anæmia from other causes, may, I am inclined to believe, be correctly explained on the same principle that applies to the above cases, and it is not difficult to understand how the antecedent condition, consisting in a loss of proper density on the part of the liquor sanguinis, is brought about.

When large quantities of blood have been lost, the remainder of the circulating fluid absorbs water in order to maintain its bulk. The dry skin and extreme thirst observed in patients who have suffered from large losses of blood are doubtless indications of the necessity of supplying a sufficient bulk of fluid to afford the heart a stimulus to contraction; but when these cases have passed through the first dangers of hæmorrhage,

the anæmia which follows cannot be regarded merely as the effect of dilution of the blood, for a cause exists in that fluid which interferes with the development of the corpuscle, and keeps up the anæmiated condition.

My friend Dr. Lever, of Guy's Hospital, informs me that in cases of violent flooding he has often observed the thirst abated by frequently sponging the body with water; and there can be little doubt of the advantage of this mode of treatment, not only as a means of allaying thirst, but of saving life; for an increase in the degree of rapidity with which water is absorbed during violent hæmorrhages may make that difference in the condition of the heart which turns the scale of life in favour of the patient; nor do we possess a better means of introducing large quantities of fluid into the blood than by applying it to the extensive surface of the skin; and the stomach, as is frequently the case, may be too irritable to receive liquids. The after-treatment of these cases, as indicated by theory, would consist in the exhibition of saline purgatives and meat diet, with the use of ferruginous tonic medicines to assist in the formation of chyle rich in an element necessary to the formation of hæmatosine.

The efficacy of this plan of treatment has been long appreciated by practitioners, and its adoption is one among the many instances our profession affords of the discovery of a practical truth as the result of lengthened and tedious experience, and without the assistance to be derived from physiology and pathology, which sciences, had they participated in the elucidation, would have enhanced the value of the fact, by enabling us to deduce general principles of treatment from the knowledge obtained, and have suggested important analogies not otherwise presentable to the imagination.

The various forms of anæmia which attract the attention of the practitioner, in many of which no very obvious cause for pallor can be ascertained, will frequently admit of explanation, if the principles I have noticed be kept in mind, and inquiry made into all the possible causes which can produce a decrease in the specific gravity of the liquor sanguinis. It would appear that this decrease admits of being brought about in one of three possible ways: 1st. by removal of one or more solid

constituents from the blood; 2dly, by inactivity on the part of the exhalents, the skin, lungs, and kidney, which will so derange the balance between the ingested and exhaled fluids as to leave an excess of water in the blood; and 3dly, by an increase of the absorbent action of the skin.

The first of these conditions is present in the morbus Brightii, while in cases of anæmia caused by excessive loss of blood, the first and third conditions exist. The latter, however, though tending to produce anæmia, in all probability merely takes place in order to preserve life; and we are not yet in possession of sufficient facts to enable us to decide how far it may exist in any other cases either as an accessory or sole cause of anæmia.

If we examine the histories of anæmial cases, we frequently discover that large quantities of the solid matters of the blood have escaped from the system in the form of leucorrhœal discharge, when the whole phenomena of the disease are explicable (at least so far as the pallor is concerned) on those principles which apply to the morbus Brightii. In other cases a difficulty exists in detecting any such cause for anæmia, and in these I am inclined to believe in the existence of the second condition above mentioned; and that the changes productive of anæmia have occurred in consequence of the exhalent power of the skin having become impaired.

These cases are generally characterized by a weak pulse, the skin being peculiarly flaccid, and the surface cool, while large quantities of water pass off by the kidneys. A stimulating diet, ferruginous tonics, tepid baths, and taneous frictions, are here particularly indicated, and rapidly produce their beneficial effects.

There is another class of anæmial cases, which, though seldom seen, are still sufficiently common to deserve attention; these constitute, in fact, a form of the morbus Brightii, but as they occur in young females slightly advanced beyond the age of puberty, and are accompanied by amenorrhœa, frequently escape detection, and are treated as chlorosis, while a more favourable prospect of recovery is entertained than would be the case were the true nature of the disease known to the practitioner.

The long continuance of anæmia in

young girls who have never suffered loss of blood, and in patients affected with morbus Brightii, who have never passed red corpuscles in quantity with their urine, are facts which, when considered in connection with the analysis of the blood in such cases, sufficiently shew that the disease may be produced by an imperfection in those processes which are necessary to the genesis of the blood corpuscles. That this imperfection consists in a loss of the normal relation between the specific gravities of the liquor sanguinis and chyle, is but a necessary deduction from what we know concerning the chemical and physical conditions of these two fluids; for it is positively certain that the chyle, being of less specific gravity than the liquor sanguinis, must, as it passes into the venous system, act upon the red corpuscles so as to enter them freely; and it is equally certain that the nearer the liquor sanguinis approaches to the chyle in specific gravity, the greater will be the difficulty in supplying this ferruginous ingredient for the production of red colouring matter within the corpuscles. This being admitted, we must not forget that the anæmia caused by the positive abstraction of blood in large quantities, the bulk of which is supplied to the system by an absorption of water, is a diseased state greatly aggravated by the difficulty which must be experienced in the reproduction of red colouring matter, owing to the approach of chyle and liquor sanguinis to the same specific gravity; and our remedies should be chosen, as in other cases of anæmia, with this view. The water should be removed by purging, nutritious diet enjoined, and iron freely administered.

There is a mechanical condition influencing the degree of pallor, of which I cannot omit notice, as it forms an important element in the production of anæmia. It consists in a change in the form of the corpuscles, producing a thickening of their edges as seen under the microscope, and exactly resembling a state always to be produced artificially by the addition of dilute saline solutions to the blood after removal from the body. This I have frequently observed in the blood of anæmiated girls, and it is doubtless caused by entrance of the too dilute liquor sanguinis into the globule at the commencement of the degeneration, rendering the form of the

corpuscles such as greatly to interfere with their circulation through the capillaries, and thus contributing to the production of the pallor. As the disease advances, the corpuscles, however, are frequently observed pale and flaccid, the balance having been effected between the contents of the corpuscle and the liquor in which they float. In this stage, however, if the skin fail to discharge its function, or if blood be lost from the system, we must expect that the corpuscle will again become thickened, as, under these circumstances, the state of stasis is disturbed, and the liquor sanguinis will again enter freely, owing to its having become further degenerated by the addition of water.

In conclusion, I venture strongly to recommend the adoption of the same plan of treatment in the early stages of the morbus Brightii that is found efficacious in chlorosis and the anæmia produced by hæmorrhage, viz. chalybeate tonics, saline purgatives, and nutritious diet; being satisfied of the value of the plan, which, though not immediately calculated to remove the congested condition of the kidney known to exist in the complaint, is still of efficacy in preserving the normal state of the blood, and may thus fairly be considered as assisting in recovery. It will be obvious, from what has been stated above, that the removal of nephritic congestion should not be effected by bleeding in any form, inasmuch as it tends to produce the condition of blood which it is desirable to avoid, as a forerunner of the secondary evils of the morbus Brightii. Counter-irritation and dry cupping are the most desirable methods of relieving the kidney.

CASE OF
THE SUCCESSFUL REMOVAL
OF A
DISEASED OVARY
OF THREE YEARS' DURATION.

BY DR. FREDERIC BIRD,

Consulting Accoucheur to the Western Dispensary, Physician to the Metropolitan Hospital, and Lecturer on Medical Jurisprudence at the Westminster Hospital.

(*For the London Medical Gazette.*)

IN recording another case in which excision of a diseased ovarium has been successfully practised, it will not be

necessary to describe minutely the method of operating, inasmuch as it did not differ in any material point from that adopted in all my previous cases; and for the narration of which I may refer to preceding pages of the *MEDICAL GAZETTE*. Features of interest in the history, and of practical import in the subsequent progress of the case, presented themselves, and to these I shall chiefly refer.

Towards the end of April last, I was consulted by Miss —, who had for many months been under medical treatment, on account of a large abdominal tumor. She had recently attained her twenty-first year, and with the exception of the disease under which she then laboured, had enjoyed previous health. The menstrual function, developed at the age of fourteen, had, during the succeeding four years, been naturally performed, but at the expiration of that time, accidental exposure to damp and cold was followed by the sudden arrest of the secretion: febrile action took place, but quickly passed away, and the catamenia reappeared. From that period is dated the commencement of abdominal symptoms, which were at first those of local inflammatory action, and subsequently of ovarian dropsy. As the local pain subsided abdominal enlargement occurred, appearing in the form of a small tumor seated in the hypogastric region, rapidly increasing in size, and after the lapse of a year filling nearly the whole cavity of the abdomen. At no stage of the disease had one side of the abdomen been more distended than the other.

During the two following years she continued to suffer from the increased size of the tumor, and although she received the most judicious medical treatment, yet nothing more was effected than the alleviation of occasional local symptoms.

When I first saw her the abdomen was rather less than forty inches in circumference, and was fully and equally distended; fluctuation was distinct at every part of the tumor; resonance on percussion in the hypochondria indicated the position of the intestines; the ensiform cartilage was projected upwards, and the capacity of the chest was evidently much diminished; some little œdema of the integuments at the lower part of the abdomen existed, and there the superficial veins

were tortuous and turgid. Her general health had become greatly impaired, emaciation had proceeded rapidly, she suffered from frequent attacks of abdominal pain of a neuralgic character, from dyspnoea, palpitation, and also from nausea and occasional difficulty in micturition. Her pulse was weak and frequent; under slight mental excitement becoming irregular in volume, and intermitting.

The diagnosis of ovarian disease was not difficult, and from repeated examination I was convinced that little or no solid matter had been deposited in the cyst, and that in all probability no peritoneal adhesions were present. There were not any symptoms indicative of uterine disease, her age and previous history were alike opposed to its existence, and I did not therefore deem it necessary to carry the inquiry farther. Dr. Hamilton Roe and Dr. Andrews, who saw the patient with me, fully concurred in the opinion that had been given, and in the propriety of operating.

Circumstances, connected with the case induced me not to delay the performance of the operation: of a temperament originally excitable, her disease had rendered her yet more so, and impressed with a belief of its incurability, she had become the subject of much mental depression; as a consequence of which all means capable of supporting her general health had been neglected; her constitutional powers were daily suffering impairment, her anxiety becoming greater, and it was evident that so much prostration would soon occur as to interfere materially with the probabilities of recovery.

April 21st.—In the presence of Dr. Ferguson, Dr. Hamilton Roe, Dr. Andrews, Dr. Cape, Dr. Cursham, Mr. Phillips, and Mr. Clarke, the operation was to-day performed. The same preliminary measures had been employed as in the cases already related. I commenced the abdominal incision a little below the umbilicus, and extended it downwards about four inches: very little hæmorrhage occurred: the cyst immediately presented itself; it was grasped and punctured; and as the contained fluid was evacuated, it emerged from the cavity of the abdomen: it had a less dark colour than I have commonly observed, and the arterial ramifications were small. The pedicle was rather long, and contained

one large artery and two of less size; it was transfixed by an instrument carrying a double ligature, firmly secured, cut through, and the removal of the tumor was complete. The lips of the incision were then brought into apposition by several sutures; a thin linen roller was drawn around the abdomen, and cold water dressing applied. The ligatures were carefully plaited together, so as to form one band, and but a small portion of them allowed to recede into the abdomen: their free extremities having been secured, the patient, who had hitherto been placed on the side of the bed with the feet supported, was drawn to a more easy position.

The operation was borne almost without an expression of suffering; the pulse, which previously to its commencement had ranged at 96, was at its completion found to be 88. A little wine was subsequently given, and she was ordered

*R. Decocti Amyli ʒij. ; Liq. Opii Sed. ʒj. ;
Fiat enema statim injiciendum.*

8 o'clock (five hours after the operation).—Has not yet slept, but presents a cheerful countenance, an easy position, a quiet pulse of 93, calm respiration, and a moist skin. The enema was repeated, and after an hour she fell asleep.

22d, 2 o'clock A.M.—Pulse 80; abdominal walls more retracted towards the spine; has twice vomited; the fluid ejected containing a part of the wine given soon after the operation. It is now stated that during health the stomach could never retain port-wine. She has slept but little, though undisturbed by any painful symptom. About nine ounces of urine have been withdrawn by catheter. A small quantity of serum has passed from the lower part of the wound.

Repetatur enema statim.

5 A.M.—Pulse 88. She is still sleepless, and has some tendency to vomiting: urine five ounces. The ice, which had been ordered, is freely taken.

A pillow, the greater part of which had been moistened with *Liquor Opii Sedativus*, was placed beneath her head, and appeared to produce calm sleep, which occurred in about half an hour.

Half-past 9 A.M.—Pulse 90; the breathing is tranquil, and skin natural, but there is now circumscribed tenderness on pressure in the right iliac

region, at which part there is also some distension. The wound presents a very healthy appearance: urine six ounces.

Half-past 4 P.M.—Pulse 96. Has slept but little; there is now less distension at the lower part of the abdomen, and the local tenderness appears somewhat diminished. The cutaneous action less free.

Half-past 8 P.M.—Pulse 100. Has become rather excited; the skin is less moist, and has an increased temperature: thirst is also troublesome; and it is difficult to induce her to take the ice or water. Urine secreted during the last eleven hours 3xvj.

23d, 2 o'clock A.M.—Pulse above 100, more depressed. She is irritable and sleepless; and there is some epigastric uneasiness, and frequent eructations.

A few tea-spoonfuls of hot water and brandy were given with relief, and afterwards

Enema Amyli c. Liq. Opii Sed. ʒiss.

5 A.M.—Pulse has risen to 112; is more irritable, but not contracted. There has been but little sleep since the exhibition of the opium. Her position is uneasy; there is increased heat of skin, with the exception of that of the lower extremities; the tongue, which hitherto had presented an healthy appearance, has become covered by a thin white secretion, and has its substance more injected: pressure in the right iliac region is now productive of greater pain than previously.

Although the symptoms presented did not serve to indicate any very acute or general inflammatory action, it nevertheless seemed evident that local peritonitis existed; an opinion which was confirmed by Dr. Hamilton Roe and Dr. Andrews, who met me in the course of the day. And as it was more than probable that the increased action was in a great measure attributable to the peculiarly irritable state of the patient, and having seen that so long as the nervous excitement was restrained, and the cutaneous secretion kept up, she had progressed favourably, the indication appeared to be to fulfil these two conditions as quickly as possible. With this view, the temperature of the room, previously at 75°, was increased to 85°; ice mixed with a little lemon juice administered

in large quantities; and the following enema employed—

℞ Decoct. Amyli ʒiiss.; Liq. Opii Sedat. ʒiij.; M. Fiat enema.

11 A.M.—Pulse 120, of the same character. She has not slept, but there is less tenderness on pressure, and the skin now perspires copiously. Urine ʒiv. since the last report; 3xvij. during the last fifteen hours; on one occasion passed without the aid of the catheter.

Habeat Morphiaz Acetatis gr. j., in formā pilulæ quāque horā ad soporem.

7 P.M.—Pulse 108; the reduction in its frequency, and four hours of calm sleep, having followed the third dose of the morphia. Very copious perspiration has continued, and there is now a manifest improvement; the abdominal tenderness is considerably less, the distension slight, and the position in bed no longer indicative of pain.

12 P.M.—Pulse and general symptoms the same. Wishes for sleep.

Enema Amyli c. Liq. Opii Sed. ʒii. statim, et repetatur post horas quatuor si opus fuerit.

24th, 6 A.M.—Pulse 110; is restless. Two enemata not having produced any effect,

Morphiaz Acet. gr. iss. statim.

11 A.M.—Pulse 106; is much improved; but little abdominal tenderness is evinced even on very firm pressure; the skin still freely acts, and the tongue is less coated; appetite is returning; and the only source of uneasiness consists in the frequent occurrence of eructations. Urine during the last twenty-four hours, 3xxij.

Allowed a little arrow-root, with water, toast-water, and tea.

9 P.M.—Pulse 104; sleeping. The use of the catheter has to-day been discontinued.

25th, 8 A.M.—I visited her three times during the night, and at the two first visits found her in tranquil sleep; at the third she was awake, but quite free from all her late symptoms. At present her countenance is very cheerful, her spirits animated, the pulse firmer, but soft, and 98; skin, tongue, and appetite, as in health.

Allowed veal broth in small quantities.

8 P.M.—Passed a comfortable day, and is quickly improving. Pulse has varied from 96 to 100.

26th.—Not being able to obtain sleep otherwise, the opiate enema was made use of last evening. The bowels have to-day been relieved, having acted twice without the aid of medicines.

27th.—Without any apparent cause she has again become excited and irritable; the pulse is more rapid, and heat of skin increased, but there is no recurrence of the local symptoms.

Enema c. Opio.

28th.—Slept well during the night, and is now much improved; tongue and pulse natural, the latter ranging at 84. The lower part of the wound is suppurating; the upper is united. She now takes, in addition to former diet, beef-tea and an egg.

30th.—Progressing most favourably.

Better diet.

May 8th.—During the week that has elapsed since the date of the last report, she has continued to improve. A good diet, with animal food and three or four glasses of wine, is taken with appetite—the action of the bowels being regulated by alternated doses of Pil. Rhæi. Co. and castor-oil. The ligatures were last evening removed, and the wound has now nearly closed, a few small granulations being present at its lower margin.

June 8th.—Rapidly improving. Has gone to reside out of town.

July 18th.—The notes taken subsequently to the last report mark an uninterrupted convalescence. By the aid of good diet and country air, she has quickly acquired full strength. The wound has long since healed, the catamenial function has been naturally performed, and the bowels now maintain healthy action. The peculiar irritability from which she previously suffered has nearly altogether subsided; her spirits are far less variable, and, in short, she presents all the appearances of excellent health.

The dimensions of the abdomen prior to, and after, the operation were the following:—

	Before operation.	After operation.
Circumference of the abdomen	40 inches	23 inches
From ensiform cartilage to pubes . .	16	11

The entire weight of the tumor was 29 pounds. The contents of the sac had a specific gravity of 1007, a light

amber colour, and contained but a very small quantity of albumen. The tumor appeared to have had its origin in a single vesicle of De Graaf, as lying upon its external surface could be distinctly seen the greater part of the ovarium, which, with the exception of increased density, did not present any marked evidences of morbid change. The Fallopian tube passed up along the posterior part of the tumor to the extent of ten inches, not closely attached, but apparently connected by a fold of broad ligament; its fimbriated extremity was free, and very perfect. The sac was abundantly covered by minute vessels running in the same direction, but not freely anastomosing; they were chiefly derived from one large trunk, which passed immediately beneath the fallopian tube, but also in part from two branches of less size contained in that portion of the broad ligament in contact with the sac. The thickness of the walls of the cyst varied, being thinner at the superior portion, denser at the inferior, the parietes in the latter region having a thickness of nearly half an inch. Within the parent cyst a large number of secondary cysts were developed, for the most part of small size, and containing fluid secretion of darker colour than that by which the former was filled. The whole internal surface had a dark congested hue, and the part corresponding to the attachment of the pedicle was of an almost black colour; this appearance being in a great measure due to the presence of many venous trunks, of rather large size, into which numerous smaller vessels passed.

The expediency of having recourse to the operation of excision still remains on the minds of many an undecided question, and by some is wholly negatived. Not that there exists any belief in the potency of other remedial means, but it is said, ovarian dropsy may be both slow as to its development and painless as to its symptoms; that it may prove but an inconvenience, may not tend to destroy life, may not embitter it. Admitting that such instances have sometimes happened, it is yet sufficiently certain that they have been but rare exceptions to the common rule, and were they of frequent occurrence, they would neither aid in determining the value of the operation, nor militate

against its employment. So long as ovarian disease remains quite inert, so long as the general health is preserved unimpaired, the treatment by operation is not indicated; to all such cases the practice of extirpating the diseased organ does not rightly apply. That the great majority of cases of ovarian disease, whether left to themselves or submitted to ordinary treatment, terminate fatally in a comparatively brief period, is without doubt, and although many respected authorities of the present day differ as to the mean duration of life, yet the most extended term hitherto stated does not exceed a few years, and these for the most part are years of suffering.

Again, it is asked whether it be better to incur the liabilities to danger which unquestionably attend the operation, with the hope of obtaining permanent relief, or by palliative measures to alleviate local symptoms, and thus retard, as much as medical ministrations may, the progress of disease. How much of benefit is to be effected by therapeutic means, experience has fully demonstrated. It is a remark as old as Morgagni (*De sed. et caus. morb.*) that tapping in ovarian disease is not only useless, but mischievous; nor have the observations of subsequent authorities been opposed to such opinion. It is from the known inadequacy of the several forms of treatment that have been introduced into practice, that strong arguments in favour of excision may be drawn. The attendant dangers of the operation in properly selected cases may probably be rendered less than have been imagined: if the diagnosis be accurately made, if an unnecessarily large abdominal incision be avoided, and if the subsequent treatment adopted be in accordance with correct principles, it will I believe be found that a large proportion of cases will terminate in success. Such, at least, has been the result of my own experience; in all the cases in which I have operated recovery has been rapid and complete.

Statistical records, so far as recent cases are concerned, have been said to speak yet more favourably, and to show that even when employed within less narrow limits, the operation has been very successful. Much caution is necessary in receiving any evidence which may be founded upon the statistics as they at present exist; the number of

cases recorded is too small and too uncertain to admit of any truthful deductions. It would seem almost a thing of fashion to test the value of aught that is novel in medical science by statistical analysis. I would not presume to doubt the great utility of such means when the elementary data are known to be correct, but in the present question this is assuredly not the case. Error, or something worse than error, has been so often associated with the cases which have occurred, that to employ their published records alone must lead to false and dangerous conclusions, not only as relates to the general employment of the operation, but also to the several methods in which it has been performed. It is an easy industry to collect together the cases hitherto placed on record, to classify and make deductions from them, which may then be offered as means for the guidance of medical opinion. But where is the evidence of their correctness? Statistical tables have been more than once enlisted by those who have argued for and against the excision of ovarian tumors, and the results arrived at by each writer have been different. Many of the cases contained in such tables have been so vaguely reported, that the manner of operating, and even the ultimate results, are imperfectly known, whilst another and not less important source of fallacy arises from the fact, that a most reprehensible practice exists of suppressing the publication of unsuccessful cases. Several such have occurred, the faithful relation of which might have shed much additional light upon the operation, but are still carelessly concealed from the notice of the profession.

38, Craven Street.

POISONING BY DIGITALIS.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case of poisoning by digitalis worthy of being recorded in your journal, its insertion will much oblige,

Yours respectfully,

GEORGE WILSON, Surgeon.

3, St. Peter's Square, Leeds,
August 6th, 1844.

The patient, a healthy, robust, young man, was advised by a fellow work-

man, who enjoyed the advantage of having studied Culpepper, to take "throatwort tea" for a common sore-throat. Accordingly, he procured as much of the fresh leaves of the purple digitalis as nearly filled a quart pitcher, upon which he poured as much boiling water as the pitcher would hold, thus making a very strong infusion. Of this he drank a large tea-cupful on going to bed; the immediate effect of which dose was a long, sound slumber. In the morning he took a second cupful (which would probably be stronger than the first, from the leaves having undergone a longer maceration), and went to his employment. He felt quite dizzy and heavy; soon afterwards began to stagger, and lose his consciousness; and at last fell down in a state of syncope.

Being conveyed home, and put to bed, he vomited severely, and complained of extreme pain in the abdomen.

When visited he presented the following symptoms:—he lay supine, very cold, pale, and covered with a copious perspiration. He was conscious, but complained of violent pain in his head: the pupils were dilated.

The pulse was extremely low, three or four feeble pulsations being succeeded by a complete intermission occupying several seconds; the whole number of beats, not exceeding 38 or 40 in the minute: each stroke, though very weak, was given with a peculiar explosive shock.

He complained of great pain in the epigastric and umbilical regions, and had incessant and severe vomiting. The bowels were confined: the function of the kidneys was completely suspended: there was a considerable and constant flow of saliva.

He was ordered brandy, ammonia, &c.: warmth was applied externally, his head kept low, and, after some degree of reaction had taken place, purgatives were administered.

Under this treatment he gradually revived, but could not for several days bear the upright position. The pulse also presented its peculiar beat and extreme weakness for a similar period. After this, he gradually but completely recovered.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Thomas Sydenham, M.D. Opera omnia.
Edidit GUILIELMUS ALEX. GREENHILL,
M.D. Londini, impensis Societatis
Sydenhamianæ. 1844.

THE admirable manner in which the works of Theophilus were edited by Dr. Greenhill, and which emanated not long since from the Oxford University Press, gave us good grounds for anticipating the ability with which any other work intrusted to the care of that zealous and learned physician would be performed. Nor have we been disappointed: the present edition of the entire works of Sydenham, in the language in which they were originally published, just brought out by the Sydenham Society, and edited by Dr. Greenhill, is alike worthy of their illustrious author, their careful editor, and of the society under whose auspices they have come forth; and we most sincerely congratulate the members of that Society on their possession of a really first rate edition of the works of a man to whom all, both at home and abroad, for almost two centuries, have united to do homage. In preparing this edition for the press, Dr. Greenhill has evidently taken especial pains to perform that first and great duty of an editor, viz. to present to the reader the text of his author in as genuine a state, and as free from inaccuracies as possible. In order to effect this he has collated all the best and oldest editions, and has not swerved from these, except where a typographical error rendered it necessary to do so—we find no learned trifling, nor display of conjectural emendations. All various readings of importance are given at the bottom of each page. Besides this, the editor has added a few notes to explain any special difficulty either of word or phrase; these are brief, scholar-like, and to the purpose, showing on the part of Dr. Greenhill, unlike many editors, a greater desire to illustrate his author than to parade his own learning. Indices, both of the matters contained in the volume, and of the proper names occurring, are given; to these is added a list of the medicines and formulæ employed by Sydenham, the value of the latter being much increased by the in-

introduction of the modern botanical names, in the adjustment of which Dr. Greenhill had the important co-operation of Drs. Pereira and Royle. Altogether the edition is most complete, valuable, and beautiful.

Nor let any one think, because the name of Sydenham is in every body's mouth, that a new edition of his Works was not necessary: the fact that 110 years have elapsed since a complete edition was published in this country, would be a sufficient answer to such an objection; but besides this, we cannot help thinking that after all there are comparatively very few who know anything of Sydenham, except his name; too many are like ignorant of the rich stores of medical knowledge contained in his pages, as they are of the spirit and temper in which these pages are written. And what, after all, it may be asked, is the great charm by which those who have once made themselves acquainted with the writings of such men as Sydenham, are led to them again and again, and rise from the perusal without disgust or satiety, ever ready to renew the banquet? The charm is simply this, that Sydenham, and such as he, to use the words of Huxham, in speaking of the Greek medical writers, "kept their eyes steadily fixed on what they would describe, and have given us the true picture and naked truth of things;" and this not drawn by the hands of an untutored youth who pretends to observe and interrogate nature before he really knows what are the problems which require to be solved, and therefore what questions require to be put. Nature will give no answer to such tyros as these. But Hippocrates, and Sydenham, and Heberden, went otherwise to work; they waited until years passed in studying nature with the greatest care and assiduity, had given them, as it were, a title to speak; and as they observed accurately, so they described truthfully, and left to posterity a rich legacy, which wastes not in the using—to us a *τῆμα ἐς ἄλ*—to themselves a monumentum *ære perennius*.

In the present day, the study of the older writers is especially needed amongst us—we want models, something which the mind can at once repose on, and keep in view as worthy of imitation. Every where around us is noise, talk, and confusion; one after another crude and ill digested notions,

supported only by unblushing fronts and voluble tongues, are put forward; each yields in its turn; it would seem as if the men of the present generation had no idea that patience and calmness are necessary elements in the mind of him who would be an observer, to say nothing of a teacher. They forget that youth is the period for building up knowledge, manhood for using it, age for imparting it. This was the rule of old; what the rule is now, the hundreds of ephemeral volumes tricked out to obtain a temporary popularity for their authors, abundantly testify. And how is this state of things to be remedied? How are men to be made to believe that it is necessary to learn before they can teach? We know of no other way than by improving the education, both moral and intellectual, of the members of our profession; and, as a part of their education, we would especially place the study of the works of men who exhibit in their writings a spirit so different from that which is rife in the present day. As a means to further so desirable a consummation, we have hailed, and still hail, with delight, the formation of the Sydenham Society—May it flourish!

A BILL FOR THE BETTER REGULATION OF MEDICAL PRACTICE THROUGHOUT THE UNITED KINGDOM.

THE Preamble 1, recites various acts and charters, having reference to one branch or another of the medical profession, passed from the 3d of Henry VIII. down to the 6th of George IV., all of which, and "so much of any other act or charter as prohibits any person from practising physic or surgery in any place without license, or as imposes any restriction on the practice of physic or surgery," shall be repeated and annulled.

Clause 2 enacts, "That a Council shall be established, which shall be styled 'The Council of Health and Medical Education;' and that one of Her Majesty's principal Secretaries of State shall be a member of the said Council, in right of his office as Secretary of State; and that the Regius Professor of Medicine in the University of Oxford, the Regius Professor of Physic in the University of Cambridge, the Regius Professor of Physic in the University of Dublin, the Regius Professor of Clinical Surgery in the University of Edinburgh, and the Regius Professor of Surgery in the University of Glasgow, shall be members of

the said Council in right of their several professorships; and that the other members of the said Council shall be one physician and one surgeon, to be chosen by the Colleges of Physicians and Surgeons of England respectively; one physician and one surgeon to be chosen by the Colleges of Physicians and Surgeons of Scotland respectively; one physician and one surgeon to be chosen by the Colleges of Physicians and Surgeons of Ireland respectively; and six other persons whom Her Majesty, with the advice of her Privy Council, shall deem fit to be members of the said Council."

3. Refers to the appointment of the first Council, and enacts, "That it shall be lawful for Her Majesty, with the advice of her Privy Council, to appoint all the members of the first Council of Health and Medical Education, other than those who will be members thereof in right of their several offices; and that at the end of the third and each of the two next following years after the first constitution of the said Council, one physician and one surgeon of those first appointed on behalf of the said several Colleges of Physicians and Surgeons, shall go out of office, in such order as Her Majesty, with the advice of her Privy Council, shall direct."

4, 5, 6, and 7. Bear on the tenure of their office by official members and nominees of the Crown, and by members chosen by the Colleges; of the manner of choosing the collegial members, and of providing substitutes in cases of extraordinary vacancies.

8. Provides for the appointment of a principal secretary, and of local secretaries for Scotland and Ireland, and of clerks and messengers.

9. Treats of Salaries to the Council, Secretaries, &c. which are to be allowed by the Lord High Treasurer, or Commissioners of Her Majesty's Treasury, and expenses for travelling, &c.

10. Settles the Presidency of the Council, who is to be one of the principal Secretaries of State, who shall have the power of nominating a Vice-President from among the Councillors appointed by Her Majesty.

11. Regulates the time and place of meeting of the Council, which are to be at the will of the Secretary of State; also the number of Councillors to be a quorum, this number being not less than seven.

12. Orders that minutes of proceedings of the Council shall be kept, and fairly entered in books kept for the purpose, which shall be open at all reasonable times to the inspection of any person or committee appointed to inspect them by any of the universities or colleges.

13. Enacts "That a register shall be kept and published from time to time, under the direction of the said Council, of all persons

who shall have been examined, and shall have received, and shall exhibit before the said Council, letters testimonial as hereinafter mentioned of their qualification to practise as a physician, or as a surgeon, or as a licentiate in medicine and surgery; for which registry the Council shall be entitled to have from the person requiring to be registered a fee of *five pounds* in the case of a physician or surgeon, and a fee of *two pounds* in the case of a licentiate, which fees shall be applied towards defraying the expenses of this Act; and every person whose name shall be so registered, who shall be desirous that his name shall be continued in the published register, shall, in the month of January in every year, send to the said Council his name and place of abode, with the date of his testimonials, and the Council shall verify the returns so made to them by comparison with the register kept by them, and shall forthwith cause the names of all persons duly registered and so returned to them to be published in alphabetical order in their several classes, with their several places of abode, and dates of their testimonials."

14. Enacts "That no person, except such graduates in medicine and such other legal practitioners as are hereinafter mentioned, shall be entitled to be registered by the Council as a licentiate in medicine and surgery unless he shall have attained the age of *twenty-one* years, and shall have been examined by the Colleges hereinafter named; (that is to say) if in England, examined by the Royal College of Physicians of England, assisted by the Court of Examiners of the Apothecaries' Company, and also examined by the Royal College of Surgeons of England; and if in Scotland, examined by the Royal Colleges of Physicians and Surgeons of Scotland; and if in Ireland, examined by the Royal Colleges of Physicians and Surgeons in Ireland; and in every case shall have received letters testimonial from each of the bodies by which he shall have been examined, of his being duly qualified to practise as such licentiate."

15. Enacts "That no person, except such legal practitioners as are hereinafter mentioned, shall be entitled to be registered by the Council as a surgeon unless he shall have attained the age of *twenty-five* years, and shall have been examined by one of the Royal Colleges of Surgeons of England, Scotland, or Ireland, or the Royal College of Physicians and Surgeons of Glasgow, after such proof as shall be satisfactory to the examining College that he has applied himself to surgical studies during at least *five* years; and shall have received letters testimonial from the examining College of his being duly qualified to practise as a surgeon."

16. Enacts "That no person, except such

legal practitioners as are hereafter mentioned, shall be entitled to be registered by the Council as a physician unless he shall have attained the age of *twenty-six* years, and shall have graduated in medicine in some University of the United Kingdom of Great Britain and Ireland, or, subject to the restriction hereinafter contained, in some foreign University, and shall also have been examined by one of the Royal Colleges of Physicians of England, Scotland, or Ireland, or by the Royal College of Physicians and Surgeons of Glasgow, after such proof as shall be satisfactory to the examining College that he has applied himself to medical studies during at least *five* years, or if he is not a graduate in medicine of any such University, unless he shall have attained the age of *forty* years, and shall have been examined by the Royal College of Physicians of England; and in each case shall have received letters testimonial from the examining College of his being duly qualified to practise as a physician; and no person shall be entitled to be received for examination for the purpose of being so registered as a physician upon a foreign degree in medicine, unless the Royal College of Physicians of England, Scotland, or Ireland, shall give him a special certificate, to be laid before and approved by the Council of Health and Medical Education, that they have made inquiry into the manner in which such degree was conferred, and have ascertained that it has been granted after residence within the precincts of the same University during at least *one year*, and after due examination and upon satisfactory certificates of previous study."

17. Enacts "That it shall be lawful for the same person, if possessed of the necessary testimonials, to be registered as both physician and surgeon, and for a registered physician, or a person applying to be registered as a physician, to offer himself for examination as a licentiate in surgery by one of the said Royal Colleges of Surgeons, and for a registered surgeon, or a person applying to be registered as a surgeon, to offer himself for examination as a licentiate in medicine by one of the said Royal Colleges of Physicians, assisted in England by the Court of Examiners of the Apothecaries' Company; and every such physician or surgeon shall be entitled to be also registered upon the testimonials granted to him upon such additional examination, in such form and manner as shall be determined by the said Council."

18. Enacts that every person registered after examination as a physician or surgeon under this act, shall be admitted as an associate of the Royal College of Physicians, or as a fellow of the Royal College of Surgeons from which he shall have received his

letters testimonial as physician or surgeon, or if he shall have received the said testimonials from the Royal College of Physicians and Surgeons of Glasgow, then as a fellow of the last-mentioned Royal College; and every such physician and surgeon who shall afterwards remove from that part of the United Kingdom in which he obtained his letters testimonial, shall be required, if he shall practice as a physician or surgeon in any other part of the said United Kingdom, to enrol himself as an associate of the Royal College of Physicians, or as a fellow of the Royal College of Surgeons, of that part of the United Kingdom to which he shall so remove, for the purpose of practising there, according to the nature of his testimonials, and in each case shall be entitled to be so admitted without further examination, and on payment of the like fees of admission, and on complying with the same conditions as are required of other persons who have passed their examinations for the purpose of being admitted associates or fellows of the said Colleges respectively.

19. Enacts that the said several Colleges shall, from time to time, when required by the said Council, prepare and lay before the said Council a scheme or schemes of the course of study and particulars of the examination to be gone through by all persons applying to such Colleges respectively for letters testimonial as physician, or surgeon, licentiate, and of the fees to be taken for examination and admission into the said several Colleges respectively; and the said council shall be empowered to make from time to time such changes in any of the schemes so laid before them as to the said Council shall seem expedient; and the said Council shall endeavour to procure, as far as is practicable and convenient, that qualifications and fees for the said testimonials shall be uniform, according to the nature thereof throughout the said United Kingdom.

20. Enacts, that after the *passing of this Act* it shall not be lawful for any University of the said United Kingdom to confer any degree in the Faculty of Medicine upon any person, unless he shall have been matriculated in the same University, and shall have duly attended the courses of public lectures prescribed by the same University to students in medicine within the precincts of the same University, or of some medical school recognized by and in connection with the same University, during at least *two* years next before the granting of such degree, and shall have been examined at some time before granting such degree by the proper examiners of such University, and found by them to possess competent skill and knowledge of medicine, and of the sciences connected therewith, and of the English and Latin languages at least; and

every diploma or certificate of a medical degree granted by any such University after the *passing of this Act*, shall set forth distinctly the time which has elapsed since the matriculation of the person to whom such degree shall be granted, and the time during which, and place at which, he shall have actually studied as aforesaid, and the fact that he has passed such examination as last aforesaid.

21. Enacts that it shall be lawful for any university of the said United Kingdom to grant the degree of bachelor in the faculty of medicine, subject to the restrictions hereinbefore contained concerning medical degrees, to any student of the same university who shall have attained the age of *twenty-two* years; and that every such graduate in the faculty of medicine, being also examined and having received letters testimonial of his qualification in the manner hereinbefore prescribed in the case of licentiates in medicine and surgery, or examined and furnished with the like letters testimonial by the Royal College of Physicians and Surgeons of Glasgow, if the said degree shall have been granted by the University of Glasgow, shall be entitled to be registered by the said Council of Health and Medical Education as a licentiate in medicine and surgery, subject to such general regulations as shall be made by the said council concerning the registry of licentiates.

22. Enacts that no bye-law to be made by any of the Royal Colleges of Physicians or Surgeons of England, Scotland, or Ireland respectively, or by the Royal College of Physicians and Surgeons of Glasgow, shall be of any force until a copy thereof, sealed with the seal of the same College, shall have been laid before and approved by the said Council of Health and Medical Education.

23. Enacts that it shall be lawful for the said Council to make regulations for ensuring the registry of all medical and surgical students by the proper officers of the several hospitals or medical or surgical schools at which they shall study, and to authorize such officers to take a fee for such registration, not being more in each case than *Ten Shillings*, and for requiring all such fees to be remitted to the Secretary of the said Council, and returns to be made to them of the registration of all such students, in such manner and form as the Council shall think fit; and no hospital or medical or surgical school shall be recognized by any of the said Colleges, which shall neglect or refuse to give due effect to such regulations, after notice of such neglect or refusal shall have been sent by the said Council to the said Colleges, until the default of such hospital or medical or surgical school be amended to the satisfaction of the said Council, and all

such fees shall be applied toward the expenses of this act.

24. Enacts that where by this Act it is provided that the concurrence of more than one body is required for qualifying any person to be registered by the said Council, the examination before such bodies or his Degree or Letters Testimonial, or both, may be conducted either separately before Examiners appointed by each body, or before a joint Board of Examiners, to be appointed by each body separately or conjointly, who shall be appointed in such number, manner, and form, and shall hold their examinations at such times and places as such bodies shall, with the approval of the said Council, agree from time to time among themselves, or as shall be determined by the said Council with respect to any point in which they shall not be agreed; and where there shall be separate examinations before Examiners appointed by each body, the subjects and fees of examination shall be divided among such bodies as they shall from time to time agree among themselves, or as the said Council from time to time shall determine with respect to any subject on which they shall not be agreed.

25. Enacts that the said Council may from time to time require returns to be made in such form, and including such particulars, as they shall think fit, respecting the examinations to be conducted as aforesaid, and it shall be lawful for any Secretary of the said Council, deputed by the Council for that purpose, or for any member of the said Council, to be present at any of the said examinations; and if the Council shall be of opinion that the regulations prescribed by them for the examination and grant of letters testimonial as physician, surgeon, or licentiate, have been infringed, evaded or neglected by any of the said examining bodies, it shall be lawful for the said Council to refuse to register upon the testimonials of the body so in default, until the same be amended to the satisfaction of the said Council.

26. Enacts that, subject to the reservations hereinafter contained, no person after the *passing of this act* who is not registered by the said Council shall be appointed to any medical or surgical office in any public hospital, prison, infirmary, dispensary, work-house, or other public institution in the said united kingdom, or to any medical or surgical office in her Majesty's army or navy, or in the service of the Honourable East India Company, except in India, natives of India duly qualified according to such laws or regulations as are or shall be made in that behalf by the Governor-General in Council; and wherever by law it is provided that any act shall be done by a physician or surgeon, or medical or surgical practitioner, by whatever name or title he is called, such provision

shall be construed, after the *passing of this act*, to mean a person qualified to be appointed to such medical or surgical offices as aforesaid; and the Council of Health shall be empowered from time to time to make regulations for specifying what institutions are to be considered public institutions within the meaning of this act, and which form of testimonial shall be necessary to qualify the holder thereof for every such situation.

27. Enacts that all persons who are registered by the said Council as physicians, surgeons or licentiates, shall be exempt while practising as such from being summoned or serving on all juries and inquests whatsoever, and from serving all corporate, parochial, ward, hundred and township offices, but, subject to the reservations hereinafter contained, no person shall be entitled to such exemption on the ground of his practising medicine or surgery, who is not so registered, nor shall the certificate of any such unregistered person, given after the *passing of this act*, be received as the certificate of a medical or surgical practitioner in any court of law, or in any case in which by law the certificate of a medical or surgical practitioner is required.

28. Provides and enacts that it shall be lawful for the said Council, on the application, within *twelve* calendar months after the *passing of this act*, of any person legally practising as a physician, surgeon or apothecary, at the time of the *passing of this act*, in any part of the United Kingdom of Great Britain and Ireland, or on the application within *two* years of any person so legally practising in any of Her Majesty's colonies and foreign possessions, to cause the name of such person to be registered as a physician, surgeon or licentiate in medicine and surgery, as the case may be, on production to the said Council of his diploma, license, or certificate, or such other proof as shall be satisfactory to the said Council, that at the time of the *passing of this act* he was legally entitled to practise as a physician, surgeon or apothecary, as the case may be, in some part of the said United Kingdom, and on payment of a fee of *two pounds* in the case of fellows or associates of the said Colleges of Physicians and Surgeons respectively, and of *five shillings* in every other case, which fees shall be applied toward the expenses of this act; and during the said period of *twelve* calendar months every person legally practising as a physician, surgeon or apothecary at the time of the *passing of this act* in the said United Kingdom, and during the said period of *two years*, every person so legally practising in any of Her Majesty's colonies and foreign possessions, although not registered, shall continue to enjoy the same privileges and exemptions, and be qualified to be appointed to the same offices, and to

practise in the same manner as if this act had not been passed, and no farther or otherwise, unless registered under this act.

29.—Enacts that every person appointed after the *passing of this act* to any medical or surgical office for which he is not qualified according to the provisions of this act and the regulation of the said Council, and who shall act or practise in such office, shall for every such offence forfeit the sum of *twenty pounds*, to be recovered by action of debt or information to be brought in any of Her Majesty's Courts of Record at Westminster, or in the Court of Exchequer in Scotland, or in Dublin, within *six calendar months* next after the commission of the offence, and to be recovered in the name of Her Majesty's Attorney-General in England or Ireland, or of the Lord Advocate in Scotland.

30. Enacts that after the *passing of this act*, no person shall be entitled to recover any charge in any court of law for any medical or surgical advice, attendance or operation, or for any medicine prescribed or administered, unless he shall prove upon the trial either that he is registered under this act, or that he was legally practising in the capacity in which he claims such charge before the passing of this act.

31. Enacts that every unregistered person who shall wilfully and falsely pretend to be, or take or use any name or title implying that he is registered under this act, shall be deemed guilty of a misdemeanor in England and Ireland, and in Scotland of a crime and offence, and being convicted thereof, shall be punished by fine or imprisonment, or both, as the court before which he shall be convicted shall award.

MEDICAL GAZETTE.

Friday, August 16, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas motu veniendi in publicum sit, dicendi periculum non recuso."

CICERO

THE NEW MEDICAL BILL—No. I.

SHALL THE MEDICAL PROFESSION BE OPEN TO ALL AND SUNDRY, LETTERED AND UNLETTERED, COMPETENT AND INCOMPETENT, PHYSICIAN AND SURGEON, QUACK AND IMPOSTOR?

THERE is much in this Bill that it seems impossible to us not to approve of; there is a little wanting to make it much more complete than it is, much more acceptable to the great body of

the profession, and we venture to add, much more beneficial to the public.

We cannot for our own part understand wherefore the medical profession alone of the several professions which require specific training and the test of competency by examination, should be deemed fit to be thrown open to all and sundry who may take a fancy to practise it.

We know that it is the rooted conviction in the mind of several influential men at the head of their particular departments in our profession, that nothing in the shape of legislative enactment can be done to prevent quackery. We will grant them, not so much indeed, but a great deal in this direction: quackery cannot altogether be prevented by any legislative enactments; but it can be discouraged, and that not negatively only, by no notice being taken of it, but positively, by being branded with its proper name; by being declared illegal, and made punishable, upon prosecution, as a high crime and misemeanor, which it certainly is.

But quackery is not all; it is even the least, in matters medical, which a paternal government, having the welfare of the community at heart, has to guard against; the victims of the quack have money in their purses, and as the consequence of this they have rank in the world; they have often even title there, and they ought always to have education: they have that which is necessary for judgment in their own keeping; they ought to know sense from nonsense, reason from folly, right from wrong. When we hear, therefore, of Lady this, and of Sir Francis that, dying, the one under the infinitesimal globule of the quack Hahnemannist, the other under the wet blankets of the quack Priestnitzist, we feel little pity for them; on the jury in such a case, we should certainly be for following the example of the illustrious twelve who brought in

the pithy verdict of "Served her right," in the instance of the shrew. It is not so much open quackery which we dread, then; we might be content to leave that to its fate. But we ask, are there none dependent on medical aid save the rich and the educated? Verily there be many—a host, and it is in behalf of these,—the poor and the ignorant, who fancy that every man with a red bottle in his window, and who smells of rhubarb and cardamoms, is a physician,—that we raise our voice. And again, we ask are there no assassins in the shape of practitioners of medicine save those who write books and work miracles, and cure consumption with a few drops of fetid spirit, and ride about in their carriages, in virtue of the lies they tell, and the successful action they maintain on the purses of their dupes? And we answer again, yes, there be many; men who are not charlatans and pretenders, men who do not fly at high game or throw dice for gold, but who are ignorant of what they do, who are incompetent through want of information—who pull out the bowels of women in travail*, and throw for halfpence, that they may live.

Surely the legislature of England, in the year 1844, cannot purpose to leave its ill-educated poor to the tender mercies of every wretch who makes pretence to a knowledge of physic and surgery, or even to the hap-hazard prescriptions of chemists and druggists, who know as much of the art and science of medicine as the kitchen-maid does of chemistry, and who are just as competent to prescribe for a sick man as were the printers who threw together the types that gave *Paradise Lost* and *Macbeth* to the world, of imagining and inditing the grandest works that ever took shape within the mind of man.

* Vide the case of John Garland, lately reported in all the newspapers.

There appears to be but one opinion upon this point in the professional mind, in so far as we have had opportunities of consulting it and collecting its sentiments. The government, for the sake of all parties, must be petitioned to revise so much of the proposed bill as refers to throwing open the profession of medicine to all and sundry. Upon proper representation we cannot doubt that this point will be taken into renewed consideration, and that that which so plainly appears to be right and proper will be finally adopted. We are inclined to say so much from the excellent spirit in which the bill was proposed.

We see one grand obstacle to the declaration of the illegality of quackery, however; it is this: that all advertising of quack medicines must forthwith and necessarily cease, and that government would not be the only loser were this the case. Government, we can believe, might be found willing to give up the few thousand pounds per annum which are derived from the stamps on patent medicines, and the duties on their advertisement in the newspapers and periodicals. But the government are not alone concerned; newspaper proprietors are still more deeply interested. It is even said that several country newspapers could not exist, were the revenue they derive from the advertisement of quack medicines to cease and determine. And then the proprietors and editors of newspapers are very commonly political agents; and the party in power in our alternate Whig and Tory administration dares not offend so influential a portion of the body politic as the agents. This perhaps may lie at the bottom of the great tenderness which Sir James Graham shows to quackery. We should indeed like to see with what countenance the Right Hon. Baronet could face the editor and part-

proprietor at least of the "Cumberland Chronicle," or the "Carlisle Independent," in the prospect of an election, had he been accessory to cutting off supplies to the amount of several hundreds per annum in the shape of quack advertisements. We can all fancy the glow of virtuous indignation that would suffuse the face of the said editor and part-proprietor upon receiving the proposal of the Right Hon. Secretary for "his vote and interest," and the extreme satisfaction which the said editor and part-proprietor would have in telling the said Right Hon. Secretary that "he would see him d'd first."—Yes, the more we think of this view of the subject, the more do we incline to cherish it as containing a large infusion of truth. But it gets far into the night, and we must pause at this time, promising to discuss the several features of the Medical Bill, one after another, until we get through it all. Meantime, as we wish not to speak in the plural-singular editorial number only, but to represent the views and wishes of our friends, we shall be happy to have these for our information and guidance.

ANNIVERSARY MEETING

OF THE

PROVINCIAL MEDICAL & SURGICAL ASSOCIATION.

ON Wednesday and Thursday, the 7th and 8th inst., the Twelfth Anniversary Meeting of this Association took place at Northampton; and the proceedings, from first to last, were characterized by as much good feeling as they were distinguished by high talent. Since the last Anniversary the association has lost its former president, Mr. Hey, son of the distinguished surgeon of Leeds, William Hey, who has made the world his debtor for one of the best practical books ever written on the most useful of all the sciences to mankind. Dr. Hastings, President of the Council of the Association, filled the chair at the beginning of the meeting, for the purpose of duly inducting the president elect, Dr. Robertson of Northampton, into his seat. In his opening

address, Dr. Hastings took occasion to pay a well-merited compliment to the merits and the memory of the late Mr. Hey; and also eloquently and feelingly dwelt, for some time, on the character and labours of the late Dr. Barlow, another of the very earliest and most zealous of its supporters which the Association had lost since last year,—a man whom all alike loved and honoured.

Dr. Robertson, on taking the chair, gave some account, historical, antiquarian, and topographical, of the good town of Northampton; and found opportunity to allude, in excellent terms, to the salutary influence which such meetings as that of the Provincial Medical and Surgical Association had upon the profession of medicine. "Assembling," said the Doctor, "for purposes partly scientific, partly social, we are brought closely together, made intimately acquainted, led to know, to appreciate, and to esteem, one another; and the jealousies, estrangements, and heart-burnings, which have been too much and too long the reproach of our profession, are thus transmuted into harmony, right feeling, and mutual regard." Dr. Robertson concluded by avowing his strong faith in the destinies of scientific medicine as opposed to quackery and delusion. "Scientific medicine," he said, "which we, in our day and generation, are honestly and laboriously cultivating, is based upon, and bound up with, all truth; their destiny is the same, and their joint triumph, though long delayed, will finally be signal and complete."

Dr. Streatham, the Secretary of the Association, then read the report, by which it appeared that the Association now numbered very nearly 1800 Members, and that, all expenses paid, there was a balance of upwards of £500 in the hands of the treasurer.

The great business of the evening meeting was the reading of Dr. William Budd's retrospective Address on the Progress of Anatomy and Physiology during the past year. This address occupied three hours in the delivery, and was distinguished for its fulness, impartiality, and ability.

On Thursday morning the leading feature of the meeting was Dr. Cowan's retrospective Address on the recent Progress of Medicine and Therapeutics, which was characterized by all that gentleman's powers, so well known to the profession at large, and, in its delivery, marked by the earnestness and heartiness of the man,—qualities which are better known among his friends.

So much for the scientific and business part of the proceedings. The DINNER, on the Thursday, was the crowning festival, and set its seal on the social element in the constitution of the assembly. Here the Medici and Chirurgi were not left to themselves;

they had the society and assistance—the very able assistance—of the Mayor and magistrates, of the Rev. Sir G. S. Robinson, Bart., and of many of the clergy and gentry, of the town and county of Northampton. Nor was Apollo unrepresented in his quality of god of minstrelsy, as well as divinity of the healing art: the presence of a regimental band shewed that the descendants of the Asclepiades were not unmindful of the ancient connection between the god of music and the god of medicine; and, sooth to say, he appears to have been present with the assembly in spirit in all his attributes, as well as Hermes, who touched the lips of more than one of the speakers with the true fire of oratory.

"The Queen," "The Prince Albert," "The Prince of Wales," "The Army and the Navy," "The Bishop of the Diocese and the Church," were all toasted and drunk with brimming glasses, in spite of the lectures upon abstinence which we are wont to deliver to our patients and to the public at large; but at Northampton the great majority of us knew that we were beyond the reach of call or summons, and we therefore dared to be reasonably jolly, and to make a fair libation to Dionysus the young.

In proposing The Bishop and Clergy of the Diocese, Dr. Robertson alluded very appropriately to the natural connection that exists between the minister of religion and the minister of nature—the medical practitioner: "They might in many respects be considered as fellow-labourers in the work of mercy."

This sentiment was admirably responded to by Sir G. S. Robinson.—"It had often been his lot to return thanks for the same toast at political meetings and on other occasions where honourable mention had been made of the clergy, but on no occasion had he felt more difficulty in responding to it than this. The real value of praise bestowed depended upon those who bestowed it; and who were so well qualified to appreciate the character of the clergy as those who entered with them into the chamber of sickness, and sat with them by the bed of death—who so well qualified to say whether the praise bestowed was merited; or not, as those who witnessed the spiritual consolation offered to human sorrows, and who in their efforts to relieve the bodily suffering which God in his Providence had laid upon us all, were aware of the message of kindness, love, and mercy, conveyed to the sufferer by the good priest? The clerical and the medical professions were of a kindred character, exercising a mutual and reciprocal influence one upon the other, often called to supply each others' deficiencies, and thus become fellow-labourers in the same cause, the noblest cause which could exercise the human facul-

ties—"glory to God in the highest, on earth peace and good-will to man." There were no two professions in the country who earned their subsistence on such hard terms as the parish surgeons and the parochial clergy. There were none whose labours were of a more anxious or responsible character. There were none from whose spontaneous bounty more was expected, and there were none truly from whom that bounty was more largely received. Morals and health act and re-act one upon the other, and he might safely appeal to that assembly of scientific men, and ask what would remove the material causes of disease so soon as more correct morals, wiser habits, and a more practical view of religion. He might appeal, on the other hand, to his clerical brethren, and ask where they found the readiest access for their pastoral instruction,—whether in the wretched abodes of misery and dirt, or in the comfortable tenements of cleanliness and health? Well then might the two professions sympathise together in the good work assigned respectively to each of them, and with good reason might he hail the toast as a token of that sympathy, and as an evidence, he trusted, of future benefit to be derived from their joint exertions.

This is alike creditable to the heart, the sense, and the rhetorical powers of the reverend Baronet.

The President next proposed—"The health of Dr. Hastings of Worcester, the father and founder of the Provincial Medical and Surgical Association."

Dr. Hastings returned thanks in an excellent speech, which we regret our limits will not permit us to give entire. He thanked the meeting from the bottom of his heart. He felt that, having taken an active part in founding that great association, he was in many ways amply repaid for his trouble. He felt that it was really a marvellous association. It was now only twelve short years since they first met, a small knot of members, at Worcester. Yet during that time the progress had been so great, and the increase of members so astonishing, that they might now literally be said to overspread the country. There was now no land, from the far east to the far west, where the effects of that association were not beginning to be felt. They had during those twelve years visited different places in the kingdom, and had carried the spirit of enquiry north, south, east, and west. They had every where been well received; the universities and the marts of commerce had alike thrown open their doors to them; the great end which they proposed—the promotion of peace and good understanding, the alleviation of human misery and suffering—had still procured them a welcome. They were now met in a

midland district, which they were informed was the highest ground in England: after twelve years of existence, might they not on this the highest spot, metaphorically speaking, take a Pisgah view of their past proceedings and future prospects, and from the retrospect see sufficient reason to anticipate still greater prospective results? They might contemplate the Association under three aspects—first, in a scientific and literary point of view; secondly, as a scheme for benefiting their poorer brethren; and, thirdly, as a means of social intercourse. Viewing it in either of those aspects, there was something to assure them that they were associated in a good cause. If they looked at the transactions and publications it introduced to the members, they would perceive that great benefit and gratification had been experienced; and he trusted that the day was not far distant when in that respect greater improvements would arise, and that they would have more important matter to communicate. Who should say that the scheme of benevolence for alleviating the sufferings of unfortunate members of the profession and their families would not be productive of the best effects? It was true the scheme was yet but in its infancy; but he looked forward to the day when they should have the God-like satisfaction of knowing that they had relieved the sorrows and the sufferings of many who, but for their exertions, would have languished in want and misery. These were great things in twelve short years to have accomplished; but they did not surpass the gratification to which Dr. Robertson alluded, arising from the social intercourse that was the desirable and inevitable consequence of their annual meetings:—Friend joining with friend hand in hand, old friendships renewed, new ones formed; these were advantages of a high moral tendency, and he approved of every thing that tended to elevate the moral character of man, without which, indeed, the intellectual character became monstrous.

After this the Mayor made a speech, and Dr. Forbes (our own Dr. Forbes, of the metropolis we mean—the Provincials had it not all their own way) made a speech, Sir G. Lefevre (another worthy metropolitan) made a speech, and Drs. Budd and Cowan made speeches, and almost every body made a speech at last, and all owned they had been happy; and, to conclude in the words of our respectable contemporary, the Northamptonshire Herald, from which we have quoted largely in what precedes, "The meeting was a very interesting one, and the proceedings altogether calculated to produce a highly beneficial effect, both as regards the profession of medicine and the country generally."

UPON THE MINUTE STRUCTURE
OF THE LIVER.

BY WEBER, KRUKENBERG, and MÜLLER.

UNLIKE that of the salivary, the pancreas, mammary, and other glandular organs in which the terminal subdivisions of the excretory ducts can be readily traced as ending in free coecal extremities, the structure of the liver in man, and, to a greater or less extent, throughout all the vertebrata, is so compact and dense as to offer the greatest difficulties in its investigation, more especially as regards the real arrangement of its ultimate secerning portion, where even the elaborate researches of Mr. Kiernan leave much doubt and uncertainty upon the mind. It is with pleasure, therefore, that, in search of further information, we would direct the attention of our readers to two papers that have recently appeared in Müller's Archives by Prof. Weber and Dr. Krukenberg, upon the minute anatomy of the liver, and in which the authors have directed their attention more particularly to the point in question, namely, the mode of termination of the hepatic ducts. According to them, the latter, so far from forming distinct lobules, anastomose freely with each other to constitute a plexus, within the areolæ of which the ramifications of the arteries and vena portæ are received, or *vice versa*, that within a terminal plexus formed by these vessels the minute radicles of the biliary ducts are intercalated, so that in a scheme given by Dr. Krukenberg of the appearance of a portion of injected liver under the microscope, these different systems of organs are seen passing the one through the spaces left by the other in a manner very similar to the warp and woof threads of a woven piece of fabric.

"The smallest biliary ducts," observes Prof. Weber, "are of much narrower calibre than in other glands. They do not terminate by coecal extremities, and thus form the bases of separate lobes and lobules in the substance of the liver, but anastomose in such a complex manner with each other as to form a dense net-work of canals similar to that of the afferent capillaries, and, like it, continuous throughout, and without being interrupted by fissures and septa of cellular tissue dividing it into lobules, extends throughout the whole viscus. If any doubt remain of the truth of this assertion, as based upon the ordinary processes of investigation, we have only to examine compressed sections of the liver of the frog under a magnifying power of 30, 50, or 100 diameters, to see most distinctly, without any further preparation, the above arrangement of parts. Here the plexus formed by the

delicate biliary ducts is indicated clearly by its yellow colour, and that of the capillary vessels filling up their intervals by the reddish hue derived from the blood contained within them. The great difficulty which arose in all the injections hitherto made of the liver, was to tell whether the net-work rendered apparent by these means upon its surface really belonged to the biliary ducts, or was merely the capillary vessels filled by extravasation. To remove this doubt, Dr. Krukenberg filled the hepatic ducts and vessels upon one and the same liver with differently coloured masses, and then carefully examined the superficies as well as thin dried sections beneath the microscope. Upon the surface of such an injected liver, he says, "there appeared, within many of the areolæ of the capillary plexus, (filled with red), a yellow spot, indicating where the mass of that colour had penetrated the biliary canals. In other situations, a yellow streak was seen to pass out of one capillary areola to enter into another immediately adjoining, or else removed to some distance. In others, the yellow canals issuing from four adjacent vascular areolæ anastomosed so as to form a yellow ring, in the centre of which a red cross was visible, formed by the union of four capillary vessels. Again, I saw a distinct plexus given off, the one red, the other yellow, from the minute ramifications of the vessels and ducts, where they lay parallel to each other. Finally, upon making sections of the same liver, red plexuses bounded by yellow, and yellow plexuses by red areolæ, were numerous, distinctly visible, and abruptly defined. Whatever be the degree or extent of anastomosis of the capillary vessels, I am at all events convinced that I have truly injected the finest hepatic canals, and that they interlace with the blood-vessels in the manner just described." So far as the fact of a plexus being formed by the ultimate ramifications of the ducts is concerned, it will be observed that both authors already cited agree with the descriptions given by Mr. Kiernan; they dissent, however, from the opinion of the latter, that this, which they regard along with him as constituting the true ultimate secerning substance of the gland, is parcelled out into lobules by septa formed from prolongations of Glisson's capsule; and still more decidedly do they disagree with Professor Müller, who, basing his views principally upon the progress of development of the liver in the frog and common fowl, states that the last biliary ramuscles end as coeca, appended to the ducts in a racemiform fashion; and in a series of observations in the same number of his journal, containing strictures upon the researches of Weber and Krukenberg, insists further upon this as the true arrangement,

by an appeal to the conditions of the liver in the Polar bear, after maceration, and its distinctly lobular structure in a great number of other vertebrata. For our own part, we are more strongly in favour of the evidence afforded by the facts of comparative anatomy, and the study of the gradual development of glands, than of that dependent upon injection alone, as the most certain method of arriving at the truth. Now that the beautiful investigations of Mr. Eowman upon the minute anatomy of the kidney, the next most complex glandular organ to the liver, have revealed to us the real structure of its Malpighian bodies, and shewn that they consist essentially of small masses of vessels contained within the dilated cæcal extremities of the uriniferous tubes, it is difficult, reasoning from analogy, to conceive that an entirely different arrangement of parts has been introduced in the formation of the liver. We think it highly probable that it will yet come to be determined, that the extreme ends of the ducts of the human liver, like those of the kidney, remain distinct from each other, devoid of any intercommunication; and that they derive the elements of their secretion from plexuses of different vessels, constituted by the artery and portal vein, surrounding, or being received within, their walls.—*Müller's Archiv.*

INFLATION OF THE LUNGS OF AN UNDELIVERED INFANT SUCCESSFULLY PRACTISED.

By J. COUPER, M.D. of Newcastle, Delaware.

Mrs. F——, having over-exerted herself, was delivered of twins at the end of her eighth month. The labour was slow, but not remarkable in any respect. The first child was a breech presentation, the spine being directed to the left acetabulum of the mother. When the head came to pass the superior strait, the cord was compressed by it, while the expulsive pains became less active than they had been. Soon after this, the pulsation of the cord ceased entirely; the usual convulsive struggle of the child followed; and then all was still. What was to be done in such a case? The spine of an eight months' child would not safely bear the force necessary to an immediate extraction. There was not time for the action of ergot. The face was not yet low enough readily to allow the fingers to be placed on the sides of the nose, that air might have access to the mouth. Nor would the mere presence of air have availed, for the child had already become still. In this state of things I executed a plan I had before determined on, and for which I had prepared myself, namely, to *inflate the lungs*, without attempting to extricate the child by force. For this purpose

I introduced my left fore-finger, and with the point of it drew down the chin. Then, using the finger as a director, I passed one end of a long elastic tube, one-fourth of an inch in diameter, well into the mouth, and taking the other end into my own mouth, I blew briskly through the tube two or three times, and immediately I had the satisfaction to see respiration established. Muscular efforts followed, and as these stimulated the uterus to stronger contractions, the labour soon came to a happy conclusion. The tube was kept in the mouth of the child until delivery was accomplished.—*New York Journal of Medicine*, May 1844.

[The practice recommended by Dr. Couper is old, as the editor of our American contemporary shows; but we believe it is too little borne in mind, and that many children are lost through neglect of bringing it into play, who might be saved by its means.—*Ed. Gaz.*]

ON VEGETABLE ACIDS

AS CORRECTIVES OF ACIDITY OF STOMACH.

By ST. TRACY, M.D.

DR. TRACY had himself suffered much from acidity of stomach, and as usual sought relief from the free use of carbonate of soda; but in vain. Alkalis having failed, he now tried the influence of acids, and having taken a glass of lemonade, he at once found relief: by and by he substituted vinegar for lemon juice, and, by using vinegar pretty freely with his food, he soon recovered his digestive powers, and his general health completely. The same remedy Dr. Tracy now recommended to several of his patients and friends, and with uniformly beneficial results.—*Amer. Journ. of Med. Sciences*, Apr. 1844.

FASCINATION.

THE late Lord —— had a daughter, who, falling ill at Bath, was attended by the late Mr. ——. Of course he soon persuaded her that she had a stricture of the rectum. The young lady wrote to her mama in town an account of her case, and of Mr. ——'s procedure to cure her. Mama communicated this to papa, who not liking the thing much, went straight to an eminent practitioner, who showed his Lordship the great improbability of his daughter being affected in the manner indicated; and made him aware that Mr. ——'s patients were all—man or woman, matron or maid—presumed to be affected with stricture in the rectum, and treated accordingly. His Lordship was in a great fume; he would not even write; he posted off the same evening to Bath to rescue his child from the malapragis, as he believed it, of Mr. ——. But what ensued? The London surgeon received a letter in a couple of days from

Lord —, to say that his Lordship felt his visit to have been quite a providential one; that Mr. — had not only satisfied him that his daughter had a stricture of the rectum, but that he himself had one, and that he meant to remain at Bath to have it cured!

INFLUENCE OF WEALTH AND POVERTY ON MORTALITY.

THE time-honoured opinion that poverty is conducive to longevity—that the rich are less favoured with the blessing of health than the poor—finds no confirmation in statistical investigations. That the hardy and contented poor man is exempt from the diseases of the wealthy and luxurious, is but a poetic fiction. Irresistible evidence of this truth is contained in every document by which the rate of mortality among large numbers can be correctly ascertained. Hence, taking the whole population of a country, wealth may be assumed as a true measure of happiness, and consequently of health; and indigence as the measure of unhappiness, and consequently of disease.—*Ferry, in New York Journal of Medicine, May 1844.*

SPEEDY WAY OF RAISING A BLISTER.

TAKE a watch-glass of the size of the proposed blister; drop into it from eight to ten drops of the liquor ammoniac. Have ready a piece of fine linen rather smaller than the watch-glass; lay it neatly into the hollow of the glass, and immediately apply this to the skin freed from hair. In a very short time, sometimes in from thirty to forty seconds, a red circle appears round the glass, and the blister is formed.—*DARQ, in Gazzetta Med. di Milano, Feb. 1844.*

UNIVERSITY OF LONDON.

FIRST EXAMINATION FOR THE DEGREE OF BACHELOR OF MEDICINE—1844.

The following Candidates have passed this Examination:

FIRST DIVISION.

Bompas, Joseph Carter....	Medical Schools.
Cadge, William.....	University College.

THE
LONDON MEDICAL GAZETTE,

BEING A
WEEKLY JOURNAL

OF
Medicine and the Collateral Sciences.

FRIDAY, AUGUST 23, 1844.

REPORTS,
BY H. FEARNSIDE, M.B.,
OF
CASES TREATED IN UNIVERSITY
COLLEGE HOSPITAL.
(For the London Medical Gazette.)

Hypertrophy and dilatation of the heart ; obstructive disease of the aortic, and regurgitant disease of the mitral, valves : pneumonia in the right lung, and principally in its upper lobe ; gastritis ; enlargement of the liver ; granular degeneration of the kidneys.

J. R. M., æt. 50, admitted into University College Hospital, under Dr. Taylor, May 20, 1843. A man of moderate stature and stout conformation : he has spent a considerable portion of his life in tropical climates, having left England when about 25 years of age. He spent three years in Demerara, and was afterwards for seven years a resident on the Island of Jamaica : at this time he appears to have lived freely, drinking on an average a bottle of Madeira daily : whilst here he suffered from intermittent fever, and had also an attack of yellow fever, from which he did not recover for two months : during the attack he was blistered upon various parts, and a number of boils appeared upon and around the blistered surfaces. After leaving Jamaica, he was for some time in New York, and whilst there was seized with malignant cholera, and narrowly escaped with his life. Leaving this part of the world, he spent some time in Arabia, and during his sojourn there had an attack of dysentery, from which he slowly recovered after the lapse of several months. Certain projects which he was anxious to carry into execution induced him subsequently to visit the East Indies and Australia ; in both of which parts he spent a con-

siderable time. But only meeting with disappointment and failure, he returned to England about six or seven years ago. Since this period he has had no settled means of life ; his means have been gradually dwindling away ; he has fallen into difficulties, and during the last four months he has often been in want of the common necessities of life ; having repeatedly passed two or three days without food of any kind, and a penny loaf has not rarely furnished the whole of his support for an equal length of time.

He appears to have enjoyed a more than average degree of physical vigour, which he partially attributes to his having for many years adopted the practice of daily bathing. He has no hereditary tendency to disease, so far as he is aware. Previously to leaving England he had an attack of rheumatism, but has not since had any return of the disease.

He thinks that during the last two or three years his health has not been so good as formerly ; he did not, however, remark any special departure from the natural state until about four months ago : the symptom which first attracted his attention was a peculiar numbness of the left arm, succeeded by a loss of sensibility on the left side of the face, which was not constant, but occurred at intervals, and was not accompanied by any impairment of the motor power. About, or soon after, this time he began to suffer from dyspnoea, which was at times very distressing : for the relief of these symptoms he was bled and took mercury, and these measures had the effect of relieving him considerably. During the last two or three months he has frequently had convulsive twitchings of the muscles of the left arm ; and within the same period boils have appeared upon various parts of the surface ; he states that they were first seen in the neighbourhood of a part to which a blister had been applied. During the last month in particular he has had much cough and dyspnoea, and has suffered much from palpitation of the heart.

When he first entered the hospital he complained of great dyspnoea, and palpitation of the heart, and he had almost incessant vomiting, which had existed for two or three days previously: these symptoms subsided under the use of hydrocyanic acid, henbane, and effervescing draughts.

May 22d.—The countenance is anxious, and the complexion sallow; he appears desirous of shunning observation. Complains of a sense of weariness and languor, and also of inability to sleep; his slumbers being short, and disturbed by frightful dreams. The skin is dry; the surface of the body generally, and especially upon its anterior aspect, is covered with great numbers of boils in various stages of their progress; most of them are small, with indurated bases, and of a dusky-red colour; in some parts several have coalesced, producing irregular elevations.

He still has a good deal of numbness about the left arm, and especially about the extremities of the fingers; the slight convulsive movements are also at times very annoying.

The respirations are 16 per minute, and unembarrassed; he has no pain about the chest, and not much cough, but he frequently expectorates small portions of tenacious, dark-coloured, muco-purulent matter, sometimes streaked with blood.

The sound on percussion is duller beneath the outer extremity of the right clavicle than beneath the corresponding part of the left one; and the breath sound in inspiration is somewhat bronchial under both, but especially under the right clavicle, where also some muco-crepitant rhonchus is heard. Posteriorly, the whole of the right side of the chest is duller upon percussion, this appearing to be more marked superiorly than inferiorly: on both sides the respiratory murmur is feebler over the upper part, but over the lower part of the lungs it is distinct, and is almost puerile upon the left side, but it has a bronchial character upon the right side.

The impulse of the heart is too forcible, and felt over a larger space than natural; there is increased dullness on percussion over the cardiac region. A morbid sound is heard with the systole of the heart, both over the apex and base of the organ, but most distinctly over the latter; it is also heard over the arteries of the neck. There is no palpitation of the heart at present, and the rhythm of its action is regular; pulse 104, soft and feeble.

The gums are pale and turgid; the mouth rather sore; the tongue is very pale about the tip, but covered along each side of the centre with a strip of yellow fur: he complains of his mouth feeling clammy, and his taste being perverted. He still occasionally vomits a yellow bitter fluid; he has much

desire for acids; no appetite; bowels confined. The liver extends about a hand's breadth below the margin of the ribs; there is no increased dullness in the region of the spleen. He has no pain or tenderness upon pressure over any part of the abdomen. The urine is pale, clear, and in reaction; sp. gr. 1015, and slightly albuminous (containing about $\frac{1}{4}$ th of its volume of coagulated albumen).

Treatment, and subsequent progress of the case.—A bitter infusion, with hydrocyanic acid, was prescribed; and also a purgative of calomel and extract of colocynth. The patient had no return of the palpitation; he occasionally suffered from dyspnoea during the night, but not at any other time; he had no pain about the chest, but sometimes complained of a sense of oppression; the cough was always trifling, but the expectoration increased in quantity, and was composed of two distinct portions—one was opaque, grey, devoid of air, and appearing to consist principally of pus; the other was a thin, dark-brown liquid. After the patient had been two or three days in the hospital a coarse crepitant rhonchus was heard over the greater part of the right side of the chest, and the dullness on percussion became more obvious; he was then directed to take 5 grains of hyd. c. cretâ three times daily, and the mixture was discontinued; but, from his own irritability and waywardness, his medicine was very irregularly taken. His pulse was usually from 90 to 100, and the number of respirations 14 to 20 per minute; he has never any headache, but constantly complains of inability to obtain any sound sleep; his nights were passed in a state between sleeping and waking, from which he was frequently roused by some terrifying vision. His strength, which was much reduced upon his admission, gave way still further. Being dissatisfied, he left the hospital on May 27th, and died suddenly two days afterwards.

Examination of the body, forty hours after death.—(The autopsy was obtained with some difficulty, and took place at the lodgings of the deceased.)

Exterior.—The body was much emaciated; there was considerable rigidity, especially of the lower limbs; the swelling and redness of, and around, the boils had in a great measure disappeared; the muscles were firm and well developed, but very pale.

Permission could not be obtained to open the head.

Chest.—There were some rather recent adhesions between the costal and pulmonary pleura over the upper part of the right lung, and the pleura on this part was thickened and opaque; but elsewhere it appeared to be healthy. About three or four ounces of slightly bloody serum was contained in each

pleural sac. The *left lung* was of an ash-grey colour externally; it was dense, being engorged with frothy serum. Every part was crepitant, but less so than in health. The *right lung* externally was of a grey colour, mottled with dark blue spots; nearly the whole of the lung, and the upper lobe in particular, was dense, exceedingly lacerable, contained but little air, and not much blood; on a section it presented a uniform deep grey colour. The anterior and inferior margin of the lower lobe was pale, soft, crepitant, and did not contain any fluid: in the substance of the lower lobe, near this part, on sections being made in different directions, four or five small collections of pus were discovered: the size of some of them was about equal to that of a grain of barley; others were smaller. The weight of the whole lung was obviously much increased. The lining membrane of the bronchi of both lungs was reddened, and the transverse fibres were more than commonly visible; much frothy serum was found in the interior of the tubes.

The *pericardium* was healthy, and contained little or no fluid. The *heart* was much enlarged, probably weighing 16 or 20 ounces; the walls of the *left ventricle* were at least equally thick as in the healthy state, and its cavity was much dilated; there was some thickening and opacity of the mitral valves, and the *musculi papillares* were unusually developed; the aortic orifice was somewhat dilated; its valves were thickened, especially towards their attachments, but rather thin towards their free margins. The *right ventricle* was not enlarged; the pulmonary valves were exceedingly thin; no *corpus arantii* existed upon any of the segments, and one of them was perforated near its free border; the tricuspid valves were healthy, and the orifice rather large. Nothing abnormal was detected in the *auricles*. There were considerable fibrinous coagula on the cavity of the left ventricle. The *aorta* was dilated, and its inner surface roughened; the internal membrane being elevated by an opaque yellow deposit beneath it, extending above the whole of the ascending aorta: there was a narrow strip of punctiform redness, and at one spot about $\frac{1}{4}$ th of an inch above the aortic orifice there was an elevation upon the lining membrane, apparently produced by the effusion of lymph; it was about four lines in length, and two in breadth; it was closely adherent to the subjacent membrane, except at its margin.

Abdomen.—The *stomach* was distended with gas; the peritoneal coat was rather dark coloured; the mucous membrane was of a uniform deep slate-grey colour—it appeared to be softer than natural, and was covered with a thick coating of mucus; in

the large curvature, and about three inches from the pyloric orifice, there was a circumscribed spot of an inch and a half in diameter, where the redness appeared to be composed of fine points; the larger vessels being less affected.

The *liver* extended for about three inches below the margin of the ribs, and upwards into the chest as high as the lower border of the fifth rib; its under surface, and anterior margin, for the depth of a couple of lines, was of a blackish blue colour, and the same hue was perceptible in spots both upon the upper surface and in the substance of the organ; internally it was pale, not granular, exceedingly firm and dense, but its cohesion was readily overcome. The gall-bladder was full of thin, very dark-coloured bile.

The *spleen* was not enlarged, and it contained but little blood.

The *kidneys* were small, being not more than half their usual size: on stripping off the capsules, small portions of the cortical substance were raised with them, leaving the surface rather coarsely granular; and these granules were seen to occupy the whole of the cortical substance, which was dark coloured, and in some parts exceedingly thin.

Remarks.—One of the first circumstances calculated to arrest the attention in this case, was the marked sallowness of the complexion, and the anxiety and restlessness of the countenance; which at once led to the suspicion of the presence of some severe organic disease. On examination, there was found to be evidence of hypertrophy and dilatation of the left ventricle of the heart; which was indicated by the increased dullness on percussion over the cardiac region, and the extended and forcible impulse of the heart, which was felt principally in the situation of the left ventricle: there was also some valvular disease. The murmur with the systole of the heart might have been produced either by regurgitation of blood into the left auricle, or obstruction to its passage into the aorta: the fact that the morbid sound was heard more distinctly over the base than the apex of the heart, and its being audible over the course of the blood-vessels, pointed out that its principal seat, at any rate, was in the aortic valves; although it is more than probable, from the state of the mitral valves which the autopsy disclosed that some regurgitation of blood into the left auricle did take place.

In the lungs, there were well-marked indications of the consolidation of the tissue of the right one, and that this chiefly affected its upper part—this was evidenced by the dullness on percussion, and bronchial character of the respiration. These signs, taken in connection with a review of the circumstances in which the patient had been

placed for some time—actual want, and its concomitant train of evils—the fact that he had been failing in health for some time before he fell into this state of positive misery—the slight cough, and the mucopurulent expectoration, sometimes containing blood, appeared at first to render it probable that the condensation was owing to the presence of tuberculous matter in the lung. But, in the course of a day or two, the existence of inflammation in the right lung became more unequivocal; the dulness on percussion over the lower and posterior part of the side became more obvious, although still less considerable than over the upper part of the lung, and a coarse crepitant rhonchus became audible over various parts of the side. In reference to this subject, it may be worth remarking, that there was an almost entire absence of any criteria but the physical signs by which the pneumonia could be detected; the pulse, though accelerated, was weak; there was no pain in the chest, nor any unnatural heat of the integuments; dyspnoea was only occasionally experienced, and a sense of oppression about the chest was complained of but a short time before he left the hospital.

In addition to the above-mentioned diseases of the lungs and heart, several of the abdominal viscera were also diseased. There was great irritability of the stomach, as evidenced in the almost incessant vomiting; but although long-continued abstinence does tend to induce a low inflammatory condition of the mucous membrane of the alimentary canal, yet the symptoms in this case did not seem to prove the existence of more than great functional derangement of the stomach; there was no epigastric pain or tenderness on pressure; the tongue (though a fallacious guide) was pale; he could take warm fluids without inconvenience, and his desire for acids arose more from the state of his mouth than any other cause.

The extent of the dulness on percussion over the right hypochondriac region indicated considerable enlargement of the liver. The patient had spent a large part of his life in hot climates, which are known to be peculiarly apt to impart a disposition to hepatic disease; he had also been in the habit of indulging freely in intoxicating liquors, which, in common with other liquids slightly or not at all nourishing, are absorbed by the veins, and must, in transit to the heart, pass through the liver.

The constantly albuminous state of the urine, and its rather low specific gravity, rendered the existence of granular degeneration of the kidney highly probable; although it does not appear to have at any time given rise to the production of dropsy. Viewing *this disease* as being due to the deposition

of lymph of low vitality in the texture of the kidneys, we might refer its origin to the period when nutrition especially began to suffer, in consequence of defective nourishment; it may be connected also with the existence of the cardiac disease, since observation has proved, too, that the affections are frequently associated.

The eruption of boils upon the surface of the body, is interesting, when viewed in relation with the impairment of the quality of the circulating fluid, both from defective supply of new material, and also from one of the principal emunctories of the system failing in its purifying action. From the operation of both of these causes it is easy to conceive that the blood must have been altered in quality, and instead of affording that appropriate pabulum which each part of the system requires for its nourishment, a fluid was exuded in particular localities, not adapted to take on the specific organization of the part, but irritating, and giving rise to local inflammation. The same observations will apply to the occurrence of a similar eruption in the decline of the attack of yellow fever, from which the patient had formerly suffered; as the composition and character of the blood are known to be greatly changed from the normal state in this disease.

As a result of this diseased condition of so many organs, the nervous system of the patient was unduly sensitive—as was manifested in his irritability of temper—intolerance of sound—insomnia, or broken and disturbed sleep—in his abrupt mode of speech, and the spasmodic starting of the limbs.

The *prognosis* in this case was very unfavourable, from the number and serious character of the organic diseases under which the patient was suffering; and still more so from the extent to which the constitution had suffered from privation, and from the depressed state of the nervous system.

In the *treatment*, the first indications were to allay the palpitation, dyspnoea, and sickness; and these being fulfilled, a mild bitter was given to improve the tone of the digestive organs. But as soon as the existence of pneumonia became certain, this was discontinued, and mercury was exhibited; this being a more suitable remedy than antimony, on account of the general depression of the patient, the irritability of his stomach, and especially because effusion into the texture of the lungs had already taken place—a pathological state over which antimony appears to exert but little power. It is to be regretted, that, from the self-willed character of the patient, no system of treatment devised for his relief was fully carried out.

The post-mortem examination of the body disclosed one or two circumstances of con-

siderable interest. No tubercular matter was found in the lungs, although, from the symptoms and physical signs observed during life, its existence had been suspected. The greater part of the tissue of the right lung was in a state approaching closely to grey hepatization, and in some situations there were small collections of pus; the upper lobe of the lung was (contrary to the rule) more affected than the lower ones; and this explains the supposition, previously mentioned, of the existence of tubercles.

The greater part of the structural lesions found in the heart were such as had been anticipated; but, in addition, the mitral valves were found somewhat diseased, and might have had a share in the production of the morbid sound heard over the apex of the heart during the life of the patient, but as the left auricle was little, if at all, enlarged, it is not probable that regurgitation of blood, to any extent, occurred into its cavity.

The slate-grey colour of the mucous membrane of the stomach may have been owing to alteration of the blood in the tissue of the part, by transudation of its fluid parts, or the chemical agency of the liquids which may have been in contact with it. But taken in connection with the diminished consistence of the membrane, it appears more probable that there had been some inflammation; the punctiform redness near the pyloric orifice was more unequivocally of an inflammatory character.

ON DISEASE OF THE BRAIN, TERMINATING FATALLY,

THE RESULT OF COUP DE SOLEIL, OR
INSOLATION.

BY JAMES WHITEHEAD, M.R.C.S.E.
Surgeon to the Manchester Lying-in Hospital, &c.
(*For the London Medical Gazette.*)

ALTHOUGH instances of cerebral disease similar to the following are by no means of very rare occurrence, whether in regard to their symptoms or their pathological characters, yet may the two subjoined cases be deemed not altogether uninteresting, inasmuch as they appear to have originated from a cause which is generally believed to be almost inoperative in this climate, and whose influence, consequently, is not at all times adequately guarded against.

CASE I.—A family residing at Manchester were spending part of the summer of 1843 in the neighbourhood of Didabury, a delightful and healthy

district on the banks of the Mersey, and about six miles from the town. On the 11th of July, the day being exceedingly fine, the atmosphere serene and clear, the children were out playing in a hay-field, and exposed for several hours to the beams of a powerful sun. The youngest, a boy twenty-five months old, was, like the elder ones, romping about without hat or other covering to his head. In the evening he was observed to be unusually lively and boisterous, and continued awake, though not fretful, till a late hour. During the night he awoke several times, wanting to drink, and at seven o'clock the following morning complained that he was poorly. Some light food was immediately procured for him, which he refused; and it was discovered that he had lost the power of speech: he could not afterwards be persuaded to utter a word. He was considered to be very forward in talking, and whilst awake seldom ceased to exercise this faculty.

Betwixt 8 and 9 o'clock he was seized with convulsions, and immediately brought to Manchester, where I saw him at half-past 9. He was at that time violently convulsed from head to foot, the features contorted in every possible way, and the shocks, which seemed to be synchronous with the movements of the heart, produced a short groan at each return. The most active treatment was at once put into practice, but the convulsions never abated, except for two or three minutes after bleeding, until a few minutes before death. He died at 2 o'clock, seven hours after the loss of speech, and from twenty to twenty-four after the exposure. He had never before had any illness.

On inspection, the pia mater on the surface of the hemispheres was turgid, but the substance of the brain appeared healthy. The ventricles contained about an ounce and a half of fluid. The medulla oblongata, pons Varolii, and neighbouring parts of the base of the brain, appeared to be covered by a deposition of adventitious membrane betwixt the arachnoid and pia mater. This appearance, however, was no longer visible on raising the arachnoid membrane, which appeared healthy; but the pia mater was in the highest state of vascular turgescence. The abdominal viscera were all quite healthy.

CASE II.—On the 11th July, 1844, I was requested to see an infant five months old, labouring under convulsions, and who had, on the same day, been brought home from the neighbourhood of Altrincham in Cheshire, where the family had been a few weeks residing for the benefit of change of air. The child, whom I had known from birth, was a fine, plump, healthy boy, and had never had any indisposition of consequence until the present seizure. On the day but one previously, the weather being exceedingly fine and hot, the baby was nursed about the garden and farm-yard, with his cap occasionally off, for two or three hours during the middle of the day, exposed to the rays of a scorching sun. Several times the nurse's attention was attracted by his holding his breath, and fixing his eyes intently for a long time together, and then sighing very deeply and slowly. This was frequently repeated during the afternoon and evening; and before bed-time it was thought advisable to put him in a warm bath. During the following day these "staring fits" returned several times, and in the evening he had a slight attack of convulsions. On the following day (the 11th), appearing in no way improved, he was brought to Manchester. A dose of castor oil had in the meantime been administered, by which the bowels had been freely operated upon. At my first visit the child had nothing particular in his appearance, except that his countenance was somewhat more pale, and he was not so lively as usual. Knowing nothing at that time of the previous history of the case, and believing that he might be suffering from the irritation of teething, or from improper diet, he was prescribed a dose of the *Mist. Magn. c. Rhæo* twice or thrice a day, and *Hydr. c. Cretâ* at bed-time. On the 12th and 13th he seemed better, but was said to have had several slight convulsions. The tongue was very slightly furred; pulse 100. On the 14th he was much worse, the convulsions having come on in the night, and continuing to recur every twenty or thirty minutes. The whole body was violently affected: the eyes turned upwards and to the right side, the mouth drawn in the same direction, the pupils dilated, snorting in the breathing, and *slight foaming at the mouth*. Pulse between 60 and 70. Ordered a leech

to be applied to the mastoid process on each side of the head. *Hyd. c. Cretâ*, *Pulv. Rhæi*, aa. gr. ij., 6tis horis sum. *Lotio frigid. capiti appl.*

15th.—The bleeding seemed to have afforded relief, as the convulsions were not so strong, and less frequent. He appeared to be a little conscious during the intervals between the fits; swallowed greedily a few spoonfuls of milk, which, however, was soon after rejected. The bowels had been freely acted upon.

16th.—The convulsions were as strong as ever, and returned every ten minutes—sometimes more, sometimes less—and in the intervals he sank into a state of coma. He seldom opened his eyes; swallowed with difficulty; sickness not so frequent; pulse 70. As the bowels had not acted for twenty-four hours, a dose of castor oil was ordered. From this period to the 20th the convulsions increased in frequency and severity, and affected the right side of the body considerably more than the left. Pulse 60 to 70.

On the 21st he was in a state of coma, pupils contracted, pulse upwards of 100, and afterwards much quicker. He died on the 23d.

Inspection.—On taking away the calvarium, the brain, which on its surface was healthy to all appearance, subsided considerably, projecting laterally over the edges of the divided skull. On this account the whole mass was removed with the greatest possible care. On the hemispheres being allowed to fall gently asunder, the corpus callosum tore through along its left side, into the corresponding ventricle, and a quantity of clear fluid rushed out, carrying with it several flocculent shreds, which looked like flakes of coagulable lymph. The hemispheres were then carefully supported towards each other, and the corpus callosum cautiously raised, with a view to examine the subjacent parts; but the whole central mass was so soft and pulpy, that the posterior commissure broke down, and the rest of the fluid escaped from the ventricles, carrying along with it the fornix in shreds like half coagulated albumen. The septum ventriculorum could not be distinguished. The corpora striata, the thalami, and neighbouring parts, were all equally soft and pulpy. The medulla oblongata and pons Varolii were covered with a deposition of thick adventitious

membrane, the former being so pulpy as to break down on being handled.

The pernicious influence of the sun's rays upon the brain and nervous system in hot climates is well known, and due caution is habitually observed in guarding against it. Nor does there appear to be any reason why, in our own more temperate latitudes, impressions fully as effective in their action should not be experienced, since the mischief arises more from the sudden change from one extreme to another, and the operation of influences to which the constitution is unaccustomed, than the absolute amount of heat or light which, by gradual initiation, it can be inured to withstand. Disastrous consequences resulting from the application of light alone, whether solar, electrical, or artificial, when of considerable intensity, and especially if the eye for some time previously have been accustomed to an obscure medium, are not unfrequently met with in the form of retinitis, which has been known to extend to the brain, and to terminate fatally. The heat of the sun is known to have a powerful effect upon the cutaneous surface, producing erythematous inflammation, eczema, &c. accompanied often by alarming constitutional disturbance, vomiting, diarrhoea, fever, and even delirium. Guérard recites, that in 1819, whilst some Swiss soldiers, in garrison at Lyons, were on parade, during the middle of a hot sunny day, a great number of them were suddenly seized with dimness of sight and headache, accompanied by various other symptoms, such as nausea, vomiting, loss of appetite, fever, &c.; and numerous instances of the kind are elsewhere on record. Cruveilhier (*Nouv. Bib. de Méd.*) gives the case of a man, aged 42, who, after exposure to the sun whilst walking in a procession without his hat, was seized with headache, which was very violent, and became intermittent. It continued six weeks, after which it ceased, but left amaurosis. Then followed fever, and death. Another case is given by Dr. Abercrombie (*On the Brain*, Case 68), of "a young man, aged 15, who, after bathing in the Tweed, lay down on the bank and fell asleep, without his hat, exposed to the intense heat of the sun. On awaking he was speechless. He was bled, &c. and the next day recovered his speech, but lost it again at

intervals several times during the three or four following days. He was forgetful, and his look was dull and heavy; he complained of uneasiness in the back part of his head. After a few days more he had squinting and double vision, with a very obstinate state of the bowels, and his pulse was 60. After farther bleeding, &c. the pulse rose to 86; but he sank gradually into coma, and died on the 30th"—twenty-five days after the seizure.

Out of twelve hundred and sixty-six cases of insanity, which M. Esquirol has arranged in tabular form, twelve are noted as having been caused by insolation, or sun-stroke. Sedillot (*Journ. Gén. de Méd.*) cites the case of a child, seven years of age, who was playing in a court-yard surrounded by white-washed walls, from which the rays of the sun, which shone full into the inclosure, were powerfully reflected. He was attacked with convulsions, and died in half an hour. On inspection, effusion was found to have taken place upon the hemispheres of the cerebellum. Van Swieten regards insolation as capable of producing impressions which may prove speedily fatal:—"Si non bene tecto capite æstivis solis radiis homines diù exponuntur: unde pessima et sæpè subito lethalis phrenitis nascitur." He relates, in illustration of this proposition, the cases of two reapers, who were lying down on a heap of hay with their heads uncovered, and exposed to the intense heat of the sun, both of whom shortly after died:—"A sociis expergefacti titubabant, incondita quædam obmurmurabant, et paulo post moriebantur ambo." (*Phrenitis*, t. ii.) In another passage the same author quotes from Boerhaave (*Comment. t. iii.*) the case of a man who, by insolation, had a violent fever, which soon merged in hydrophobia*. It is useless multiplying quotations, which might be carried to a considerable extent.

The practice which has for a length of time prevailed, and even grown into a kind of fashion, of turning out infants to the powerful influence of a summer's sun, at the age of a few months, without hat or other covering for the head, is injudicious in the extreme. Under pretext of hardening their heads, the little creatures are exposed, through the summer months, at the windows, to the direct rays of the

* *Dict. de Méd.*, art. *Lumière*, par Guérard.

sun; and in the garden or play-ground, without any artificial protection whatever, and long before nature can have furnished an adequate one of her own production. Since my attention has been more carefully directed to this subject, I have frequently met with cases of febrile irritation, accompanied by diarrhœa, languor, fretfulness, &c.—sometimes vomiting, drowsiness, and convulsions—having come on while the child was in the nurse's arms, at the window or in the garden, and which could be traced to no other cause but exposure to the sun.

A case was under my care, of cerebral disease, which terminated fatally two or three days since, in a child two years old. The illness commenced on the evening of an intensely hot day, four or five weeks ago, the child having been exposed for several hours, in the middle of the day, on the sea-coast. The first symptoms were nausea and vomiting, deep sighing, loss of appetite, rolling of the head during sleep, &c. I was called in four days only before death. The symptoms then were, partial coma, alternating with fits of incessant whining and fretfulness; occasional vomiting; pulse 140; pupils dilated—the left larger than the right; occasional squinting; mouth slightly drawn to the right side. The day before death the pulse had risen to 180; she was in a state of coma from which she could not be roused; pupils contracted; mouth much distorted; eyes suffused. Six hours before death convulsions came on, and seemed to cease only with life. An inspection could not be procured.

Manchester, Aug. 2, 1844.

ON
A NEW CRANIOSCOPY,

UPON A SCIENTIFIC FOUNDATION:

A Lecture delivered at Leipzig, on the 3d of February, 1841,

By DR. C. G. CARUS,
Medical Privy Councillor, and Physician in
Ordinary to His Majesty the King of
Saxony, &c. &c.

TRANSLATED FROM THE GERMAN,

By J. C. H. FREUND, M.D.

[Continued from p. 629.]

(For the London Medical Gazette.)

It may here be well to premise upon
what grounds these new craniosco-

pical researches are based, in what respect they do not entirely lack a strictly scientific foundation what results may be expected, what inferences drawn from them, and what amount of circumspection becomes necessary in applying the principles thus obtained for the purpose of forming a judgment upon the organization of individuals. It must be left to the physiologist, and to the medical practitioner who claims the name of physiologist, to make the applications in individual cases; but at the same time, the greater part of the educated public will be put on that level which will enable them to follow, though it may be from some distance, cranioscopic investigations with a due degree of respect and interest, and to permit them to escape the risk of remaining sceptical whether researches and studies of this kind are to be mixed up with sneer-criticism, (interpretation of dreams) and the trumperies of chiromancing gypsies.

It becomes, at this point, of the utmost importance to have at least some clear conception of the most difficult part of physiology, viz. of the functions of the nervous system, and its relation to what we call the conscious soul (*bewusster Geist*). All that can be said of the meaning attached to the parts of the brain, and the structure of the skull, naturally receives its support from this source.

If it be true—and our intrinsic consciousness of truth, provided we be capable of perceiving it, assures us that it is so—that every living creature as a whole, or constituting what we are wont to call an organism, is, like the apparent world, “dependent” for its creation on an eternally creating divinity; on a spiritual eternity (*Geistiges Urbild*) on the very idea of what is to be created, it necessarily follows that the human organism must have such a spiritual eternity for its primeval and original cause. This spirit, this idea is it, that shews itself in the appearance of our organized body, from the first microscopic commencement to the gradually increasing development of the human form. It shews itself partly as a living thing unconscious of itself, partly as something which has acquired consciousness, appearing as the *psyche*, and at last in its supreme perfection as a reasoning spirit.

That which we therefore call our

organic structure is nothing but the reflection of that primary divine spirit represented within a *natural thing*, which progresses gradually according to certain most remarkable laws through a constant series of changes of its elements.

This spiritual eternity in our being, which is the cause of the organism becoming *such a one as it is, and no other*, is alluded to by Goethe in these lines :

"According to the law to which thou owest thy being
So must thou be—thou canst not fly thyself;
Nor time nor pow'r can e'er to atoms break
The minted form that once has come to life."

The more delicate, the more homogeneous in itself, the more semifluid the structure which is produced by this creating principle, the more is it influenced by every unconscious or conscious stimulus of that divine original; and this is the reason why what in the organism gets hard and substantial, becomes much less susceptible of those stimuli, and consequently much less active, than that part which retains the semifluid consistence and thoroughly impressionable quality. The part, therefore, that is most imbued with life, and that best represents the idea of the organism—in one word, the most *psychical* system of the organism—will be that which continues or remains constantly in that soft and semifluid condition; it will be that to which we give the name of *nervous system*. If a clear idea is desired of the nature of the relation which exists between the conscious processes of the psyche, and the central organs of this system, we need only recollect how necessarily and most essentially the whole variety of our sensuous impressions is dependent on the minute and semifluid extension of one of those sensuous nerves. Take, for instance, the open eye of an animal, and looking at the particle of the grey and soft retina which receives the impression of light, say to yourself:—just as the whole sphere of our impressions of sight is necessarily connected with a similar particle of such nervous substance as its organic representative, so in the same manner is every psychical life that has obtained consciousness connected with the wonderfully delicate organization of the brain, as its organic condition; and it is but thus that a correct idea is obtained of the relation which takes place between the nervous

structure and psychical life. Although what has just been said may suffice in general to afford at least *some* idea of the organic meaning of the nervous structure, it will be necessary to call to mind some other points of the doctrine of the nervous system, so as to ascend in our knowledge to the comprehension of a new kind of *cranioscopy*, founded on scientific principles.

We refer here, first of all, to the following fact. The most accurate experiments by the aid of the microscope have shown that this nervous substance is of a double nature, one very different from the other; there is, namely,

1. An *original* nervous substance, upon which depends the very first germ of the brain, the spinal chord and the nerves, a substance that remains essentially in the brain, consisting of very fine microscopical vesicles or cells.

2. A substance which is of *consecutive* origin, constituting entirely the system of nerves properly so called, and at the same time a very great portion of the brain and spinal chord, consisting of fibres of the utmost delicacy of structure, recognizable only under the microscope. If we apply the term of *innervation* to that quality of the nervous system which becomes apparent and active in organic life, then we have further to remark that it is in the primitive fibres alone that the conductive power or stream of this *innervation* exists, while it is a fact that it is the primitive and vesicular substance which governs the *development of this innervation*, and gives rise also to the various internal incitations to that faculty, called by us the *conductive* quality of innervation, which may be now augmented, and now diminished in degree. We therefore see that the same difference which occurs in the organic structure of both substances also shows itself in the sphere of their functions.

Further, as regards the conductive innervation of the fibrous substance, it is partly *centrifugal*, that is, *proceeding* from the brain as its centre; and partly *centripetal*, that is, *recurring* to the brain. (See figure top of next page.)

The latter (*a*) is the cause of sensation, and conveys to the brain all the impressions of the external senses; on the former (*b*) is dependent the reaction of the nerves or other organs in general, and the incitation to active function especially. All that I have just stated

can be practically proved according to physical laws. A section or ligature of those nervous fibres which are acting *centripetally* (*c*) at once interrupts sensation, and does not allow any sensuous impressions to reach the mind; and any division or ligature of the centrifugal fibres of other nerves (*d*) immediately intercepts any possibility of reaction, and especially that of motion.

But with respect to the development and the tendency of innervation continually remaining in, or adherent to, the vesicular substance of the brain, we are obliged to yield a certain amount of belief; and even here it can be proved by experiments that a certain relation takes place between this constant tendency and the surrounding world, as regards those impressions which remain unimpeded.

Suppose, for instance, the optic nerves to be destroyed; certainly from that moment there will not enter into the psychical life any new impression of sight, but those visual impressions which formerly have taken place will nevertheless remain. People who have lost their sight, in some way or other, fancy or dream, for a very long period afterwards, that they really are able to see like other men, and it is only in children who have lost their sight that any rapid transformation of the original cerebral substance is followed by an early loss of the optic impressions which had been made up to that time. Persons who have suffered the loss of a limb by amputation retain from the same reason very distinctly all the impressions of the removed extremity, so far even as to experience a sense of pain in the extremity that is gone.

From all this it becomes evident that some modification of the tendencies of innervation is domiciled, as it were, and retained in the brain, which is to be considered as the conductor and inciter of impressions generally.

Finally, it must be remarked, that it is not only the fibrous substance of nerves which enters the brain for the external centrifugal and centripetal streams of innervation, but that there also

gradually develops itself in the brain a peculiar fibrous substance which penetrates with endless radiations every region of its original vesicular substance, and synthetically unites the whole system, which substance, the more it is elaborated, so much the more does it become bound up with the unity of psychical life. It is thus that all impressions must be brought into relation one with another, and thus connected in the most perfect manner with the unity of the psyche.

After these explanatory remarks, we are enabled to enter more closely into the different formations of the brain by which this most important organ of a psyche that has attained to consciousness of itself makes its appearance in the whole animal kingdom, including man. Here we have likewise to call to mind some points which are particularly characteristic:

1. In those animals which are not conscious of psychical life, or in which there exists only an obscure consciousness of the external world, we find that the nervous substance which is to represent the brain, and from which the optic nerves only take their origin, is generally but a simple and roundish nervous knot (*a*).

2. In the superior animals, in which more distinct impression and sensation of the external world are developed, and where, commencing with fishes, and passing through reptiles, to birds and mammalia, all the three important capacities of psychical life, namely, *perception*, *feeling* (the sphere of the passions), and *will*, become apparent with certainty; though, what is most supreme, the possession of a reason-

ing spirit is never obtained, the structure or formation of the brain divides itself throughout into a trinity, and every where are we enabled to distinguish very clearly three different masses of the brain, to which we apply the names of anterior, middle, and posterior cerebrum.

the brain, being likewise of considerably greater size, and of finer structure; while the middle portion, on the contrary, remains limited both as to place and development.

1, Olfactory, 2, Optic, 3, Acoustic nerves.

4. The human brain, in its gradual development, is a true repetition of the forms met with in the lower orders of animals; in the embryo of two months it resembles that of fishes, and it acquires its full size at the period of seven years, but continues, as regards the inward structure of its fibres, in a progressive state towards perfection. On the circumstances above mentioned, namely, on the gradual increase of the brain's tripartite development, we base our statements by which we think ourselves justified in saying—(and thus we are approaching to a most important circumstance for the foundation of a scientific system of symbols as regards the brain)—that these essential masses of which we have given the different descriptions do not only vary with respect to the origin which they give to the nerves, of the great sensuous organs, but that they do so as regards their *psychical meaning*.

The middle portion of the brain, peculiar even to animals which have either no consciousness of themselves or are only conscious of the world surrounding them, is in the higher orders of the animal kingdom likewise the representative of the obscure and unconscious psychical life, or in other words of obscure *sensibility*; the anterior part of the brain—which rises in its development in proportion as does the faculty of perceiving, and attains, in man, under the name of the hemispheres, an enormous degree of development—represents *perception*; the posterior part of the brain,

Of these three cerebral substances the middle part most reminds us of the simple cerebral knot which we meet with in the lower orders of animals, and which it resembles thoroughly in giving origin to both optic nerves.

From the anterior brain the olfactory nerves arise; and, throughout the whole animal kingdom, the more the faculty of perception, the intellect, of the animal is developed, in like manner, step by step, do we witness corresponding superiority in this portion of the brain.

From the posterior brain the acoustic nerves proceed. These are the nerves of the sense most capable of conveying the finest psychical impressions—it is the most highly spiritualized sense; and the posterior cerebral knot is situated next to the spinal chord in which the primitive fibres of the extremities are united, that is to say, the most essential conditions to motion.

3. The same tripartition, as regards its essential nature, has the human brain, with this distinction, that the proportion of its masses amongst themselves is very different, the anterior part of the brain obtaining an enormous size and development, and the posterior, in its proportion to the middle part of

which receives the nerves of the motory senses, taking its position next to the commencement of the spinal chord, represents *volition*; or, in other terms, the decisive power on every kind of reaction towards the external world, the incitement to every motion that is to follow, the impulse in general to every kind of action.

The distinction of each of these three substances, and consequently that of their respective signification or meaning, is necessarily the more perfect the less strong the relation which is worked out amongst these three masses by the higher development of the interior fibrous tissue of the brain; at the same time, it must be evident that the more intimately the three masses become connected between themselves by endless conducting arches, the more diminished also, and even entirely suspended, becomes that local relation which originally existed between the three fundamental capacities of psychical life, and the three parts of their organic representative; viz. the brain.

From the same reason, it will be easily understood that in animals of a lower order, where the brain abounds less in an interior fibrous tissue, and in that unity which is everywhere conspicuous in this structure, physiological experiment best succeeds in proving the local relation which exists between the different tendencies of the psyche and the organs of the brain. The French physiologist, Flourens, who, perhaps, instituted most carefully the greatest number of experiments, by depriving animals, and especially birds, of separate parts of the brain, has found, throughout his experiments, that the abstraction of the anterior part of the brain throws the animal into a death-like state of stupefaction and drowsiness, with a suspension of all perception; and in the same manner we can convince ourselves, in experimenting upon young mammalia, that pressure or abstraction of the hemispheres is immediately attended with the same state of sopor. And, on the other hand, Flourens has seen that the abstraction of the posterior brain (the cerebellum) was invariably followed by suspension of all regular motion, whilst the perception of external objects remained perfect and unimpaired. He very justly remarks as follows on the symptoms which appeared on that abstraction: "C'est une

chose surprenante de voir l'animal à mesure qu'il perd son cervelet, perdre graduellement la faculté de voler, puis celle de marcher, puis enfin celle de se tenir debout."

But of a dove, which continued to live a very long period after being deprived of its cerebral hemispheres, or the interior brain, he speaks in the following terms:—"Figurez-vous un animal condamné à un sommeil perpétuel, et privé de la faculté même de rêver durant ce sommeil, tel à peu près était devenu le pigeon auquel j'avais retranché les lobes cérébraux."

Experiment, then, confirms, in the most decided manner, what the comparative anatomist pronounces upon the brain's development, as the original primitive organic representation of the threefold disposition of all higher developed psychical life, *perception*, *sensibility* (the feelings), and *will*. The tripartition of the cerebral mass must take its origin in the anterior, the middle, and the posterior brain; but it must be remarked, that it only gives origin to the organic expression of a psychical tripartition, and as such is primitive; but, at the same time, the more the interior organization of fibres operates in its progressive development to establish an unity of the whole cerebral structure, the less can one think of ascribing a certain disposition of the psyche to a certain and circumscribed portion of the brain. If anything were wanted to prove the absurdity of Gall's doctrine, in which he attempted to establish that certain tendencies of the soul which have been most unlogically separated (for instance, the faculty of comparison, that of locality, secretiveness, ideality, theosophy, &c.) are to be seen expressed on some part or other of the surface of the cerebral mass, and organically confined and circumscribed—if there were nothing else, I say, to disprove that doctrine, it would be evident, from the foregoing observations, that in the superior orders of animals the more the brain itself progresses towards its development and perfection as one whole, so much the more do the three primary and grand divisions of psychical life become less and less dependent upon the three original masses of the brain as regards their signification*.

[To be continued.]

REMARKS ON
PROFESSOR LIEBIG'S VIEWS OF
THE COMPOSITION OF URINE.

BY GOLDING BIRD, A.M. M.D.
Assistant-Physician to, and Lecturer on Materia
Medica at, Guy's Hospital.

(For the London Medical Gazette.)

SEVERAL statements in the recently published researches of Professor Liebig on the normal constitution of urine*, especially command attention, no less on account of the high reputation of their distinguished author, than from their militating against some of the most generally received opinions on this subject. I now venture to offer some remarks on the following points, which possess, perhaps, greater interest than many others.

1. The presence of hippuric acid in the urine.

2. The functions of the tribasic phosphate of soda.

1. *Hippuric acid*.—We are almost exclusively indebted to Liebig for all the knowledge we possess of this substance. Long mistaken for benzoic acid, the latter was stated by Scheele to be a constituent of the urine of infants at the breast, and by Rouelle, to exist in that of herbivorous quadrupeds. These errors admit of very ready explanation in the circumstance that hippuric acid becomes converted into benzoic by the process of putrefaction, and hence if the urine examined by the above chemists had been kept for some time before analysis, benzoic acid would be of necessity generated. On account of the great readiness with which hippuric acid crystallizes, and its very insoluble character, it is a matter of surprise that it has never been previously detected in the urine of the human adult. Lehmann has indeed announced its presence in diabetic urine, but this was regarded as almost peculiar to the disease.

There cannot exist the slightest doubt of the accuracy of Liebig's statement of the presence of this acid, as it may be readily obtained by the process he has suggested. I find the following plan to be somewhat easier in execution than that recommended by the professor of Giessen.

About 20 ounces of urine are evaporated over a charcoal-chauffer or sand-

bath to about an ounce. Nearly three drachms of strong hydrochloric acid are then added, and the mixture is boiled nearly to dryness. When cold, about two ounces of water are poured on the mass, and the whole well and repeatedly stirred. A brown solution is formed, and must be decanted from the insoluble residue, which consists chiefly of a mixture of hippuric and uric acids. Some of this deposit may be boiled in alcohol, and the filtered fluid allowed to evaporate in a glass capsule, when needles of hippuric acid will be left. Or a portion may be placed in a test-tube, digested with a little ether, and a few drops of the ethereal solution evaporated spontaneously in a watch-glass will leave thin and delicate needles of hippuric acid. So very readily does this acid crystallize, that from a drop or two of the alcoholic or ethereal solution, three or four delicate four-sided, exceedingly slender needle-like prisms, half an inch long, may be obtained. Sometimes these needles are not visible at first in a satisfactory manner, but after a few hours they increase in size and become beautifully distinct.

As hippuric acid, although infinitely more soluble than the uric, requires about 400 times its weight of cold water for solution, it cannot find its way into the urine in any quantity unless combined with a base, and this in the majority of instances appears to be soda, all the alcoholic hippurates being very soluble. It is now a well-recognised fact, that benzoic acid, when taken as a remedy either free or combined, is not, like the citric, tartaric, acetic, and other vegetable acids less rich in carbon, converted into carbonic acid, but uniting with a nitrogenised substance, is converted into hippuric acid. This substance was supposed to be lactate of urea, and thus the change was at once satisfactorily explained; but this hypothesis must be abandoned, if Liebig's opinion of the absence of lactic acid in urine be correct.

The proportion of hippuric acid existing in urine has not been ascertained; Liebig has supposed it to be equal in quantity to the uric. This has, however, not been the case in the experiments I have made; the utmost proportion obtained by myself never exceeded in quantity one-third the uric acid present. If hippuric acid be formed in the organism from the nitrogenised

* Lancet for June 1st and 8th, 1844.

elements of the food, we must expect it to be inconstant in quantity; as must, indeed, be every element of an excretion whose origin is traced immediately to a metamorphosis of the ingesta.

It may, however, be reasonably asked whether hippuric acid may not under certain circumstances perform another function, for its composition certainly suggests the probability of its being the vehicle by which carbon may under certain conditions be eliminated from the system. Although the essential function of the kidneys is unquestionably to filter off highly nitrogenised elements from the body, yet these organs can, as every case of inflammatory jaundice teaches, for a time compensate for the deficient functions of the liver, and eliminate bile from the blood; the urine hence becoming of a deep porter colour, and bitter. But in cases where the functions of those organs whose duty it is particularly to separate carbon from the blood (the liver and lungs), is merely partially interfered with or imperfectly performed, it would be very interesting to ascertain whether the kidneys compensate for these deficiencies, by eliminating carbon from the blood in the form of hippuric acid. An examination of the urine in cirrhosis of the liver, and in an extreme case of pulmonary empyema, would probably afford an answer to this interesting question*. A comparison between the per centage composition of dry hippuric acid, and the analysis of Dr. Kemp of the organic constituent of human bile, will shew the analogy between them, *quoad* the proportion of carbon:—

Human Bile†.		Hippuric Acid‡.	
Carbon . .	68.40	63.93	
Nitrogen . .	3.44	8.21	
Hydrogen . .	10.13	4.64	
Oxygen . .	18.03	23.22	
	100.	100.	

2. Tribasic phosphate of soda. — Phosphoric acid in combination with

* Since the above was written, a man, labouring under jaundice, came under my care at Guy's Hospital. He was an habitual drunkard, and had a contracted, probably a hob-nail, liver. The urine was pale porter-coloured, and, when concentrated by evaporation, yielded with hydrochloric acid a deposit rich in hippuric acid, being nearly entirely soluble in alcohol.

† Letter to Professor Liebig, London, 1844.

page 37.

‡ *Dumas' Traité de Chimie*, Paris, 1826, page 219.

lime, perhaps magnesia, soda, and, according to Berzelius, ammonia, has been long known as an important constituent of urine. From the analysis of the late Dr. Simon* nearly $2\frac{1}{2}$ grains of phosphate of soda are present in 1000 grains of healthy urine of specific gravity of 1.012. The phosphate of soda of urine is identical with the well-known pharmaceutical salt, and consists of—

1 atom phosphoric acid = 72
2 atoms soda . . . = 64
1 atom basic water . = 9

145 = the dry salt

24 atoms water of crystallization . } 216

361 = the crystallized salt.

On this hypothesis the atom of phosphoric acid, as generally assumed, is doubled, consisting of P_2O_5 instead of $PO_2\frac{1}{2}$. This salt becomes invested with peculiar importance from the functions assigned to it by Liebig of being the solvent for the uric (and hippuric) acid, as well as being the source of the natural acid reaction of urine. The number of opinions on the latter subject which have been published from time to time are well known; the acid reaction having been attributed in turn to uric, lactic, and carbonic acids, as well as to hydrochlorate and biphosphate of ammonia. Liebig has shewn that it is probably owing to an acid phosphate, as free phosphoric acid, produced at the temperature of the body by the action of uric (and hippuric) acid on the tribasic phosphate of soda. A solution of uric acid in water by the acid of that salt has been termed "artificial urine:" a name not very happily chosen, as such a solution bears no possible resemblance to urine save in that of containing in solution two of its ingredients. Liebig states that when 15 grains of uric acid and as much of hippuric acid were heated in a solution of 40 grains of dry phosphate of soda in a pound of water, the whole formed a clear acid fluid, and on cooling very slowly deposited half of its uric acid; "this sediment is of an analogous form to that deposited by natural urine after standing at rest for a long time."

It is well known that 8.1 grains of uric acid are on an average separated

* Franz Simon, *Medizinischen Chemie*, Berlin, 1842, B. 2, S. 286.

from the blood by the kidneys in the course of 24 hours. This quantity is contained in about 40 ounces of water, or not quite 2500 times the weight of the acid, which from the accurate experiments of Dr. Prout, requires about 10,000 times its weight of water for solution: consequently it is impossible to suppose that uric acid can exist in urine in a free state unless the existence of unknown causes modifying its solubility be supposed. Some indeed, have, as I believe, on very insufficient data, attributed this function to the colouring matters of urine. The difficulty has been satisfactorily met long ago by Dr. Prout, who supposes uric acid to exist combined with ammonia, forming a salt which requires but 490 parts of water for solution. This opinion has been adopted by most observers who are at all acquainted with the phenomena presented by the urine, and so completely supported by a great mass of evidence, that there can, I think, be no difficulty in regarding the urate of ammonia as the normal state in which at least a part of the acid under consideration exists in healthy urine, and in the coloured amorphous deposits. It frequently happens, however, especially when an inflammatory diathesis exists, that uric acid is deposited in crystals more or less coloured, and differing essentially from the amorphous deposits in merely becoming opaque, and not dissolving in the urine when heated. These crystalline deposits have been explained by the presence of some acid, which, by combining with the ammonia, precipitates the uric acid. This precipitant has been generally regarded as lactic acid, or occasionally the sulphuric. As the presence of the former in urine must now be regarded as doubtful, and even if admitted hardly explains the phenomena alluded to, some other explanation of the reason why urine sometimes deposits free and at other times combined uric acid, or, as often occurs, both simultaneously, is required. This explanation is, I think, satisfactorily found in the peculiar action of uric acid on the phosphates, to which attention has been drawn by Professor Liebig.

Having prepared some perfectly pure uric acid, I made the following experiments.

A. Ten grains of crystallised phosphate of soda were dissolved in an ounce of hot distilled water, and to the

alkaline solution thus formed, four grains of pure uric acid in minute tabular crystals were added: the whole soon dissolved, and was filtered through paper whilst hot. On cooling, a slight troubling occurred, and in twelve hours a copious crystalline deposit had taken place. This was collected and dried.

B. Under the microscope the deposited crystals were found to consist of transparent colourless prisms arranged in fasciculi and stellæ; exactly resembling a variety of crystalline deposit of not very frequent occurrence in urine, and remarkable for presenting a marked difference to the usual lozenge-form of uric acid crystals.

C. Boiled in water, these crystals did not dissolve; the only change detected by the microscope was the breaking up of most of the fasciculi, and the transparency of the crystals being lost.

D. By digestion in warm and strong hydrochloric acid, the crystals underwent no further change than when mere water was employed.

E. Ignited in a platinum spoon, after digestion in the acid (D), they burnt to a black ash with the odour peculiar to uric acid; by continuing the heat, a white fused bead was left, which dissolved in water, did not effervesce with acids, and consisted of phosphate of soda.

F. The fluid decanted from the crystalline deposit (A), was clear, and reddened litmus paper. A few drops of hydrochloric acid caused after a few minutes a deposit of uric acid in flat tables excavated at the sides, being the same form as the acid originally employed. By ignition, these crystals scarcely left a perceptible stain on the platinum spoon, and hence contained neither soda nor its phosphate.

G. Some healthy urine was mixed with hydrochloric acid, and after repeated agitation during 24 hours, was decanted from the precipitated uric acid. On examining the latter under the microscope, the crystals were found to present the form erroneously described as cylindric, being composed of very thick yellow lozenges, with the obtuse angles rounded off; so that when lying on their sides they so closely resemble cylinders that until allowed to roll over it was impossible to dispel the idea of such being their figure.

H. The acidulated urine filtered from the uric acid (G) was mixed with the fluid decanted from the crystalline deposit (A). An almost immediate

deposit occurred, which when examined by the microscope exactly resembled in figure the uric acid precipitated from urine (G), being in thick obtuse lozenges, and did not bear the slightest resemblance to the crystals deposited from the same fluid and hydrochloric acid (F), unmixed with the urine. Indeed, they only differed from the crystals (G), in being pale lemon, instead of orange-coloured.

These experiments prove that uric acid, without the presence of hippuric acid, will decompose phosphate of soda when aided by heat, producing an acid phosphate and basic urate of soda; the former causing the solution to reddens litmus, and hence giving us a key to the long-contested question of the acidity of healthy urine. Professor Liebig has further shewn that on cooling, and by repose, half the uric acid is deposited, still leaving the supernatant fluid sufficiently acid to reddens litmus paper. This deposit certainly, however, does not possess the properties of the common urinary sediment, as it is in large and well-defined crystals, and does not dissolve in boiling water, or change in hydrochloric acid, whereas the deposit in question is amorphous, readily dissolving in boiling water, and hydrochloric acid converts it into rhomboidal crystals of uric acid. The deposit from Liebig's "artificial urine" (A), does, however, so closely resemble the less frequent crystalline uric deposits, as to leave no doubt of the immediate cause producing them being identical.

The crystals spontaneously deposited (A), differ materially in crystalline form from those precipitated by hydrochloric acid (F), the former being in prisms and stellæ, the latter in thin tables excavated at the sides, a form which I have never seen in urinary deposits. The cause of this difference in crystalline form is readily explained by the spontaneously deposited crystals containing phosphate of soda in all probability chemically combined, as neither boiling water nor hydrochloric acid removed it (C, D, E). The influence of the colouring matter of urine in altering the crystalline form of uric acid is beautifully shown in the action of acidulated urine from which the uric acid had been separated (G), upon the solution of uric acid in the phosphate (H), the crystals neither being in prisms nor stellæ, but in thick

obtuse lozenges, exactly resembling those thrown down from urine by the acid, and bearing no resemblance to those precipitated from the same solution, either spontaneously, or by pure hydrochloric acid.

The property announced by Liebig of the action of uric acid on phosphate of soda, and which, as Lipowitz* has shewn, is also exerted on alkaline acetates and lactates, thus appears to lead to a satisfactory explanation of the acidity of healthy urine, and to the formation of crystalline uric acids. But to the ordinary amorphous deposits which disappear on heating the urine, and present the least amount of deviation from health, this explanation will not apply; Dr. Prout's opinion of the uric acid normally existing as urate of ammonia being most in consonance with observed facts, and sufficient to explain all the known phenomena presented by this class of deposits.

Is it possible, then, to explain the formation of urate of ammonia in the urine consistently with the opinion of Liebig regarding the source of its acid reaction? It is obvious that such cannot be done if a soda salt be regarded as the solvent; but if it be shown that a phosphate of ammonia possesses similar properties, the opinions of Drs. Prout and Liebig admit of complete reconciliation. Chemists are well acquainted with a compound, long known as microcosmic salt, which crystallizes spontaneously from putrescent urine. This salt is, like phosphate of soda, tribasic, and differs from that compound only in one atom of soda being replaced by one of oxide of ammonium: it therefore consists of

1 atom phosphoric acid .	72
1 „ soda	32
1 „ oxide ammonium .	26
1 „ basic water . . .	9

139=dry salt.

This double phosphate, or at least its elements, exists in urine, and appears among its acknowledged constituents in most of the published analyses.

I made the following experiments to ascertain how far this salt exerted a solvent power over uric acid:—

I. Ten grains of the double phosphate in crystals were dissolved in an

* Simon, *Bertrage zur Physiologischen Chemie*, Berlin, 1843, B. i. S. 97.

ounce of hot water: the solution exerted an alkaline reaction. Four grains of pure uric acid, in tabular crystals, were then added, and the mixture heated. Part only of the acid appeared to dissolve; the undissolved part evidently underwent some change, becoming snow-white and denser, the supernatant fluid losing its alkaline reaction. On cooling, it deposited urate of ammonia in microscopic needles.

K. The white undissolved portion (I) was placed under the microscope: no trace of tables of uric acid could be detected, the whole being changed into minute delicate needles of urate of ammonia. These readily dissolved in hot water, and were deposited in part on cooling.

L. The fluid filtered from the deposit (I) was neutral to test paper; on the addition of hydrochloric acid, it slowly deposited tabular crystals of uric acid. By long repose a very few prismatic crystals of the same substances were deposited without the addition of any precipitating acid.

M. The fluid separated from the deposited urate of ammonia dissolved an additional portion of uric acid when more was stirred in, and heat applied. The solution was perfectly clear, and acid to test-paper. On cooling, it deposited an abundance of acicular urate of ammonia, and after long repose also let fall prismatic crystals of uric acid.

These experiments appear to me to explain in a most satisfactory manner the phenomena presented by the urine so far as uric deposits are concerned. Uric acid, agreeably to Dr. Prout's view, exists chiefly combined with ammonia, which base I believe it obtains from the triple salt of soda and ammonia; and it is this portion which is deposited in an amorphous form by cooling the urine, or evaporating it in vacuo. Another portion of the acid decomposes the soda element of the double salt, agreeably to Liebig's opinion, and is deposited, in combination with a little phosphate of soda, in crystals by very long repose, even in closed vessels; or much sooner when an excess of the acid is separated from the blood by the kidneys. That urate of ammonia is first formed in the greatest abundance by the action of uric acid on the triple salt is shown by experiment (I), and after the deposition of this the residual fluid possesses the

property of dissolving more acid, rendering the solution acid to test-paper. Thus it is probable that when the triple salt is acted on by uric acid, its ammoniacal element is first partially decomposed, and on the addition of more uric acid its soda element partly yields; in both cases a super-phosphate is formed capable of giving to urine its natural acidity.

From this reasoning we should expect that if the proportion of uric acid present in the urine is within certain limits, it would constitute only an amorphous sediment of urate of ammonia, but that when found in large excess, as when a calculous diathesis exists, we should expect it to be deposited in crystals, and nearly in a pure state. The same theory also readily explains the very frequent simultaneous occurrence of amorphous and crystalline uric deposits.

There is one very essential difference between the mutual behaviour of phosphate of soda and uric acid, and of the same acid with phosphate of ammonia. The former salt, as stated by Liebig, is decomposed by uric acid at a temperature of about 100°, urate of soda being formed, and an acid phosphate left in solution. On cooling, this acid decomposes the urate of soda, setting free uric acid; or, in other words, uric acid decomposes phosphate of soda by heat, but in the cold phosphoric acid decomposes urate of soda. It is obvious, however, that this decomposition is but partial, otherwise Liebig's theory would fail to explain the acidity of healthy urine. Phosphate of ammonia, on the other hand, as we have seen, acts very differently (I); it is (in the state it exists in the microscopic salt) decomposed in part by uric acid when heated, and urate of ammonia is formed, on which salt the acid phosphate generated does not act by cooling. Probably the insolubility of the urate of ammonia by removing it out of the sphere of action of the acid salt, may partly explain this discrepancy between the action of uric acid on the ammoniacal and soda phosphates.

One important practical hint may be drawn from these observations; viz. the probably successful treatment of uric acid gravel by the administration of phosphate of soda. If sufficiently diluted, this salt is sure to enter the circulation and be excreted by the kidneys.

neys, thus furnishing to the urine an energetic solvent of uric acid. It is true that this indication can be generally fulfilled by the pure alkalies and their carbonates, but they too often exert the injurious effect of materially interfering with the digestive organs, and thus directly affecting the integrity of those functions most intimately connected with the production of the morbid deposit. The phosphate of soda may be given in doses of ℥j. to ʒss. thrice a day without any other apparent effect except that of slightly relaxing the bowels, and the urine becomes charged with the salt. We may thus hope to retain uric acid in solution, and gain time for the employment of those remedies which are best adapted for the treatment of the uric diathesis. For it must never be forgotten that in merely giving a remedy to hold an urinary deposit dissolved, we are merely treating an effect, and not a cause.

Before concluding these remarks, I would venture to correct one statement of Professor Liebig, which is certainly erroneous; viz., that alcohol has never been detected in the urine. In the elaborate essay of a most talented and experienced physician and chemist, Dr. Percy, of Birmingham*, an experiment is related in which a bitch was poisoned by alcohol, and traces of it were, after death, detected in the brain, blood, urine, and bile. The tests employed were the inflammability of the distilled fluid, and its power of dissolving camphor; and hence no doubt can exist as to the real presence of alcohol in the substances examined.

Myddleton Square, Aug. 6, 1844.

ON THE TRANSFORMATION OF PUS CELLS INTO A MUCOUS OR FIBROUS TISSUE.

By WILLIAM ADDISON, F.L.S.

[Continued from p. 652.]

EXPERIMENT 3.—Half a wine-glassful of pus was well mingled with an equal quantity of Brandish's liquor potassæ. The plastic matter resulting could be drawn out into strings a yard long. A delicate thermometer was immersed

in the mixture, but no rise of temperature could be detected. Sulphuric acid, previously diluted with six or eight times its bulk of water, was now added to the plastic matter, and gradually, with considerable effervescence, it became quite white, resembling coagulated white of egg*. At the end of two hours, there was a very considerable smell of sulphuretted hydrogen issuing from the materials which had formed themselves into a solid fibro-albuminous mass. This solid mass was now thrown into clear pump water, and on tearing it to pieces with two needles, I found, it resembled in all its visible characters, many of the morbid products found in the living structure; thus portions of it were like the interior of a *vomica*, especially several cavities which had been formed in its interior by the expansion of the gaseous bubbles; and many other portions resembled the pseudo-membranous layers often found lining purulent cavities. Several small shreds were examined by the microscope, and they exhibited a very copious fibrous structure; myriads of minute molecules were squeezed out from the interstices of the fibres, by pressure between the slips of glass, and these exhibited a singularly active molecular action. In some of the pieces or shreds thus examined, it was evident that the alkali had failed to rupture all the cells, so that numerous entire and more or less perfect pus globules were found incorporated among the fibres. *The fibrous tissue here formed by my manipulations could not by any visible or microscopical character be distinguished from that formed by the fibrillation of the buffy layer of the blood, or by the process of nutrition in the living body.*

EXP. 4.—A quantity of the white fibro-albuminous matter, resulting from the last experiment, was placed (after maceration for some time in water) in a glass capsule, and equal parts of liquor potassæ and water, previously mixed, were poured upon it; heat was applied, and in a few minutes the whole was again dissolved, forming a transparent solution,—*but now this transparent solution had not the slightest trace of any plasticity whatever.*

EXP. 5.—Twenty drops of pus were mingled with seven drams of water,

* Prize Essay on the Presence of Alcohol in the Brain. London, 1839, p. 23.

* I may here observe, that the alkali effervesced slightly on adding to it any diluted acid.

(about three parts of a wine-glassful); they were well stirred together: the mixture was homogeneous, and exactly resembled a very poor milk and water; there was no appearance of flaky matter whatever. Ten drops of liquor potassæ were then stirred in it, and in a few minutes copious flakes appeared; these flakes were found by the microscope to consist of aggregated cells, more or less altered, and connected together by the fibres or plastic material which had resulted from the bursting of some of the cells. Ten drops more of the liquor potassæ were added, and the whole well stirred together; the mixed materials now became quite transparent, *and they had all the glairy physical characters of white-of-egg.* On examining a small portion of this white-of-egg matter, I found in it numerous disintegrated cells; their diameter was much enlarged, and they were distinguished more by little circular masses of molecules, than by any thing like entire cells. Water was now placed in a shallow glass capsule; the plastic matter was emptied from the wine-glass into it, and heat applied. The plastic matter did not mix with the water, but remained distinct, just as white-of-egg would have done. The mixture was boiled for a few minutes, and stirred, so that the animal matter should not burn. *There was no visible alteration, except the production of a little froth; there was no coagulation from the heat.* While still warm, the transparent white-of-egg like matter was thrown into dilute acetic acid, and the formation, or rather the appearance of a distinct and coherent fibrous membrane on the outside of the mass, protecting the interior from the access of the acid, was as interesting as it was novel and remarkable.

Exp. 6.—Equal parts of pus and liquor potassæ were well mingled together in a wine-glass; they formed as before a transparent and exceedingly plastic compound—mucus or tissue. A large glass capsule was provided, holding a quantity of dilute acetic acid; also two large needles with handles, and a pair of scissors. Various portions of the plastic matter taken up on the point of one of the needles from the wine-glass, were cut off with the scissors; they were then placed in the dilute acid, and with the needles I could draw them into a variety of shapes and forms, which soon became *set*, by the forma-

tion of an opaque white fibrous membrane, from the action of the acid, and they resembled in external appearance various structures and membranes hitherto, I believe, not known to be formable by such methods.

In all these experiments, I attribute the plasticity of the transparent material to the development of a real fibrous structure, and *the event* immediately antecedent, or the cause of this fibrous structure, is the rupture of the pus-cells: the acid renders this structure opaque and visible, so that it may be seen by the naked eye, but it rather tends to destroy than to increase the strength or tenacity of the fibres*.

There is another experiment connected with this investigation which I shall now proceed to relate; it is, if possible, more interesting and remarkable than those already narrated, and it harmonizes completely with my *Theory of Nutrition*. For if the walls of capillaries undergo the changes I suppose, then their elements must be found in the secretions.

Exp. 7.—A watch-glass was half filled with dilute acetic acid, and two, three, or four drops of clear saliva, free from any air-bubbles, were allowed to fall gently into it: on carefully looking at these drops of saliva, they were found not to have mingled with the acid fluid, but each drop preserved its own figure, somewhat like oil on water, and as small portions of the plastic matter from the pus-cells would have done, there was also a faint opacity observable about each drop. A needle was inserted into this saliva, and on stirring it slightly, a small quantity of white matter adhered to the point, which I immediately recognized from its behaviour to be fibrous, and on subjecting it to an examination by the microscope (linear power 300), it was found to be an exceedingly perfect and complete specimen of fibrous structure; the fibres were each of them distinct and well-defined, forming an intricate tissue, and distributed upon the fibres, and in the structure were numerous minute molecules, such as are seen in the fibrillated net-work of the liquor sanguinis. Moreover, in some of the specimens I examined, I saw several of the mucous cells of the saliva, and a great many epithelial scales, attached to, (the former

* It is essential to the full success of these experiments that the pus be thick, white, opaque, and healthy.

altered in form), and incorporated with or among the fibres. The fibrous structure or tissue seen in this experiment, (which may be varied in many ways) is the most beautiful and perfect of any I have yet seen. Now the saliva is by all agreed to be a secretion formed by cells—it varies considerably in plasticity; and this experiment indicates that every drop of saliva contains a form of fibrous structure, which may be made visible by dilute acetic acid.

But it may be said that it was well known that acids coagulated the saliva. Yes, but a great distinction has ever been insisted on between *fibrin* and *albumen*. This distinction is very important, and I have endeavoured to observe it, by saying that *fibrin fibrillates* in assuming the visible form, *albumen coagulates*. Now, my experiments shew that mucus, saliva, and the plastic element of pus-cells, *fibrillate* in the same way that the plastic element of blood-cells does in the formation of the fibrous structures of the living body.

Finally, as a last experiment relating to this part of my subject, I may mention, that if two, three, or four drops of liquor potassæ be added to half an ounce of pure water, and then two, three, or four drops of pus be added, and well stirred, the compound has somewhat of the same degree of plasticity as saliva, and the same degree of transparency. If this be dropped into dilute acetic acid, the phenomena are similar to those observable when saliva is treated with the acid.

The conclusions I draw from these experiments, with those already announced, I am quite aware when enunciated, in the concentrated form of a principle, involve such consequences, that every energy ought to be exerted to test it ere it be received for use; from this ordeal the *new facts* will, I am well assured, come out untouched; therefore, vague doctrines, baseless theories, loose opinions, and hasty inferences, wherever originating, must give place to the *new forms of mental apprehension* appropriate to their interpretation.—I remain, sir,

Your obedient servant,
WILLIAM ADDISON.

Great Malvern, August 9, 1844.

* The strength of the acetic acid does not appear material to the success of this experiment. I found the strong acid do equally well.

RESEARCHES
CONCERNING THE
IMPORTANCE OF BILE IN THE
LIVING ANIMAL ORGANISM.

By PROFESSOR SCHWANN.

(Müller's Archiv. 1844, No. 2).

AND ON THE
FORMATION OF FAT,

By GEO. KEMP, M.D. Cantab.

WE are indebted to Professor Schwann for an account of some interesting experiments, instituted for the purpose of ascertaining whether the bile is really essential to life. These were so conducted as to allow that fluid to flow out of the body without ever getting into the bowel. The means employed was ligature of the ductus choledochus.

The author contends that the experiments of Brodie, Tiedemann, and Gmelin, Leuret and Lassaigne, are of no physiological value as regards the present inquiry; inasmuch as if the ductus choledochus be simply tied, not only is ingress of bile into the bowel prevented, but the secretion is likewise stopped. Now the secretion may serve a double end in the animal economy; first, to remove certain matters from the blood; second, to elaborate a fluid destined, like the gastric juice, to exercise some peculiar action upon the nutriment. That the bile contributes to effect a change in the composition of the blood cannot be denied. Accordingly, if the depurative process performed by the liver be arrested, death must follow as surely as after ligature of the ureters.

To obviate the above difficulty, the author, while he applied the ligature, formed at the same time a fistula of the gall-bladder, having its external opening in the abdominal integument. Under such circumstances, if death ensued, it must be from absence of bile within the bowel, for the secretion is permitted to go on without interruption: those cases, of course, being excepted where a fatal termination has been the immediate result of the operation.

There are various ways of ascertaining whether death has been so caused. The most direct is cadaveric inspection. We may thus determine whether it is to be ascribed to inflammation of the peritoneum in consequence of the opening made into its cavity, or to inflammation of the liver through in-

flammatory action commencing at the ductus choledochus, and thence spreading into the parenchyma of the viscus. The latter, indeed, is apparent during life by the icteric signs. The second means of knowing if death depends upon the wound is the period at which it ensues, and the condition of the wound at that period. The third is by numerical comparison of the successful and unsuccessful cases. On the whole, when properly conducted, the operation is not more hazardous than the Cæsarean section, and, as our author quaintly remarks, dogs can bear much.

It is important to prevent as much as possible the re-establishment of the ductus choledochus, or any escape of bile into the abdominal cavity, as the latter would inevitably give rise to violent peritonitis.

The dogs submitted to operation, 20 in number, were carefully weighed daily, or every few days afterwards. This affords another indication of the amount of the animal's sufferings; for the weight alters very little the three

first days, when the operation has been skilfully and successfully performed. The influence of the absence of bile is not perceptible until a later period. When, however, the dog loses weight considerably soon after the date of the operation, it is a proof of serious damage; and death generally follows, though not always, from direct injury.

The dogs are apt to lap the bile as it flows from the fistulous orifice, and this finding its way into the stomach, might be supposed to exert some influence either in promoting or retarding digestion. Purkinje and Pappenheim remarked that artificial digestion was impeded by the presence of bile. To counteract, therefore, any risk of mischief from this source, the author attached a piece of sponge to the orifice by means of caoutchouc, so as to imbibe all the fluid discharged. This precaution, however, did not seem to produce any difference.

Subjoined is a tabular statement of the experiments illustrative of the essential importance of the bile.

Dog.	Age.	Result of Operation.
No. 1	Adult	Death 17 days after the operation from want of bile. Continued diminution of weight from the operation until death.
No. 2	Adult	Cure through reproduction of the ductus choledochus. At first, diminution; then increase of weight.
No. 3	Adult	Death 3 days after the operation from peritonitis and jaundice.
No. 4	Adult	Death 7 days after the operation from peritonitis.
No. 5	Adult	Death 80 days after the operation from privation of bile. At first, diminution; then increase; finally, again diminution up to the period of dissolution.
No. 6	Young	Death 7 days after the operation from want of bile.
No. 7	Adult	Death 5 days after the operation from peritonitis.
No. 8	Adult	Death 2 days after the operation from peritonitis.
No. 9	Very young	Death 2 days after the operation from peritonitis.
Rabbit	Adult	Death the day after the operation.
No. 11	Adult	Death 25 days after the operation from want of bile. Continued diminution of weight.
No. 12	Young	Cure through reproduction of the ductus choledochus. At first, diminution; then increase of weight.
No. 13	Adult	Death 6 days after the operation from peritonitis and jaundice.
No. 14	Adult	Death 2 days after the operation from peritonitis.
No. 15	Adult	Death 5 days after the operation from peritonitis.
No. 16	Adult	Death 7 days after the operation from peritonitis.
No. 17	Young	Death 64 days after the operation from want of bile. At first, diminution, then increase, and eventually diminution of weight till death.
No. 18	Adult	Death 13 days after the operation from want of bile. Continued diminution of weight.

For perspicuity's sake, the above may be classed under three heads:—

1st. Experiments in which healing took place.

2d. Those where death happened, or

might have happened, through the operation.

3d. Those where death occurred independently of the operation.

To the first head two only can be

referred; namely, Nos. 2 and 5. In both of these it was seen, upon cadaveric examination, that reproduction of the biliary conduit had supervened, notwithstanding a considerable portion of the ductus choledochus had been snipped away. The dogs lost weight during the first six or ten days, and then regained it progressively until they weighed as much as formerly. The continuity was probably completely restored by the sixth or tenth day from the date of operation. In each instance the fistula of the gall-bladder closed spontaneously.

To the second head may be referred Nos. 3, 4, 7, 8, 9, 10, 13, 14, 15, 16; in all, 10 dogs. The woe of them died within seven days, and uniformly lost weight during the three first days after the operation.

To the third head belong Nos. 1, 5, 6, 11, 17, 18; that is to say, 6 dogs. In their case death can be ascribed only to privation of bile. They all preserved their primitive weight very nearly during the first three days after the operation, and then began to lose flesh. In experiments 6, 18, 1, and 11, emaciation advanced steadily till death, which occurred 7, 13, 17, and 25 days respectively after the operation. In experiments 17 and 5, death ensued at an interval of 64 and 80 days; and there was this peculiarity, that the two dogs, after losing weight in the first instance, recovered it again, and subsequently wasted away. In all the above cases death was preceded by symptoms of inanition, more or less marked in proportion to the remoteness of the period of dissolution.

The following important practical inferences may be drawn from these experiments. Out of 18 dogs whose ductus choledochus was tied, and fistula of the gall-bladder at the same time formed, two alone survived. In both, when killed, the ductus choledochus was found re-established. Of the other 16, 10 died in consequence of the operation. In the remaining 6 death could not be assigned to that cause, but only to absence of bile in the intestinal tube. It may be therefore concluded that the bile is of vital import; that the liver does not merely serve, through the biliary secretion, to carry off certain effete matters from the blood, but that it at the same time elaborates a fluid essential to the animal economy. This is

borne out, not only by a consideration of the six cases where the animals died without any other appreciable cause, but likewise of those in which the duct became restored and the dogs lived. There, the emaciation continued up to a certain period, no doubt that of the re-establishment of the ductus choledochus; in one (No. 12) symptoms of marasmus supervened exactly resembling those in dogs dying from want of bile, but which completely disappeared on the integrity of the conduit being regained. The ten cases in which another cause of death was discovered cannot be received in evidence, as it is probable that the privation of bile partly contributed to shorten life. This must be taken into account in every instance where an animal outlives the operation three days, as the effects of absence of bile are already appreciable before that date; if wasting occur earlier, it is probably the direct effect of the operation.

Death takes place even when the dogs lap and swallow the effluent bile; it cannot, therefore, be reckoned a substitute for that which, in the natural course of things, passes into the duodenum. On the other hand, the ingested bile did not seem to impair digestion.

Young dogs die as well as old ones, and probably sooner; thus, No. 6 died in seven days; and No. 12, although eventually saved by reproduction of the biliary canal, manifested by the tenth day those marked symptoms of faulty nutrition which do not usually show themselves till a later period.

Death takes place amid symptoms of inanition or defective assimilation,—emaciation, muscular weakness, tottering gait, falling out of the hair; and these are the more prominent the longer life is prolonged after the operation.

There is considerable variation as to the period at which animals die from want of bile; thus, one young dog died within seven days, another not before two months and a half had elapsed. The dog of experiment No. 17 survived the operation more than sixty-four days; and here the biliary channel was not found re-established on examination after death. It would appear, as a general rule, that adult dogs perish from want of bile in from two to three weeks after operation. Now it is known that dogs can live for nearly a

month without any kind of nourishment (Müller's Physiology, Bd. I., p. 477).

With regard to experiments Nos. 5 and 17, it may be presumed that the dogs in the first instance became emaciated from want of bile, but again gained flesh upon restoration of the ductus choledochus.

In order to account for those cases in which after the animals had apparently recovered, there was a renewal of the emaciation, and death, it may be assumed that at some advanced period, in consequence of local injury by a blow or leap, the newly-formed texture has been ruptured, leading to inflammatory exudation within, and closure of, the previously pervious canal, whereby the supply of bile has been cut off.

The following is the author's summary of results:—

1. The bile is not a mere excrementitious matter, but is, after being secreted, of vital necessity.

2. Bile is alike indispensable to young and old animals; indeed, the former seem to bear its want less than the latter.

3. When the bile does not get into the bowel, its absence is generally perceptible in dogs by diminution of weight about the third day.

4. When the bile is prevented from reaching the bowel, adult dogs usually die after two or three weeks, sometimes earlier.

5. Death is preceded, as above stated, by signs of deficient nourishment, great wasting, muscular debility, falling out of the hair, together with slight convulsions during the agony.

6. The bile which naturally flows into the duodenum cannot be replaced by that which the animals lap and take into the stomach.

7. The bile so swallowed does not seem to interfere with the process of digestion.

The author proposes to extend his experiments, with the view of ascertaining whether the efficacy of the bile depends upon its being a solvent of certain articles of nutriment.

In connexion with this subject we would briefly notice some ingenious speculations promulgated by Dr. Kemp, touching the formation of fat*. He

observes that the theory of Liebig, which maintains that animal fat is formed from the assimilation of the non-nitrogenized ingredients of the food, of which starch may be taken as the type, justly obtains the preference. It is, however, involved in obscurity: for, if we compare the formula of starch $C_{12}H_{10}O_5$ with the formula $C_{12}H_{10}O$, which he gives as a very correct empirical expression of fat in general, we find an excess of oxygen, bearing to the carbon the proportion of 3:4, unaccounted for; nor can we consider it sufficient to state that this large quantity of oxygen is converted into CO_2 and H_2O . In the healthy performance of the digestive functions but a very small relative proportion of carbonic acid is found in the stomach or small intestines; and, if the starch of the food is converted into fat, the excess of oxygen must enter into some state of combination up to the present time unexplained.

If it be granted that the whole of the assimilated portion of the food is conveyed through the thoracic duct into the system, it is clear that a careful examination of the chyle will furnish us with all the materials necessary for connecting the phenomena of digestion, assimilation, and reproduction. This fluid must contain in itself all that is necessary for the fresh deposit, whether of tissues or fat. Such an examination will be free from all the risks of analogical reasoning; it will be merely expressive of the condition of the whole, as representing the sum of its parts.

We are, fortunately, in possession of the ultimate analysis of the chyle, by Marcet and Macaire, which proves that the elements of this fluid are so proportioned as to represent proteine in combination with another body capable of forming fats, and legitimately expressed by an empirical formula combining the elements of starch and bile, whilst it seems most satisfactorily to establish the great importance of that fluid in the formation of fat: without its presence or efficient agency the starch might become sugar, as in diabetes, or split into the binary forms, carbonic oxide, carbonic acid, or carbonated hydrogen, as in some cases of dyspepsia, or, more particularly, in hoven cattle, but the natural organic change cannot occur.

* Theory of the Formation of Fat, by George Kemp, M.D., &c., p. 3.

The author then proceeds to demonstrate by a series of chemical equations, that if we deduct from the formula expressive of the analysis of chyle by Marcet and Macaire, the formula for proteine as stated by Mulder, we obtain a formula $C_{12}H_{12}O_6$ representative of the non-introgenized portion of the chyle; and that by the addition of two equivalents of starch to the compound representing the non-nitrogenized portion of graminivorous bile, we arrive at the same result. Hence he concludes:

"1. That, in graminivorous animals, the bile, during the digestive operation, is deprived of its nitrogen in the form of ammonia, absorbs oxygen, enters into combination with the amylaceous parts of the food, and is thus absorbed, together with the proteine compounds, in a form capable of producing all the solids and fluids of the animal body.

2. That the object of the amylaceous portion of the food is not immediately to form fat, but, by combination with the bile, to produce a compound containing the elements of fat with an excess of oxygen for cartilage, gelatine, and other allied structures which may be represented by proteine plus oxygen.

The relation between the non-nitrogenized portion of the bile of graminivorous animals and the volatile fatty acids in butter, will be immediately recognized; and the application of the above data to the probable mode of formation of milk affords some very excellent analogies which cannot be traced in this brief sketch.

A difficulty presents itself with regard to carnivorous animals; they "consume no starch, and it is evident that some element of food containing more oxygen than proteine must be present in order to form the non-azotised portion of the chyle." But as their food consists, in addition to muscular fibre, of large quantities of tendons and epiphyses of bones, or in other words, of gelatine and cartilage, the author at once surmounts the obstacle, by adding the elements of the non-azotised portion of leopard's bile to those of chondrine.

"Thus, in the combination of chondrine with the bile in carnivora, we obtain the same results as in graminivora, by the combination of their bile with amylaceous food; and the analogy of the contents of the thoracic duct in

animals differing so widely in habits is thus accounted for.

It will also be seen that the leopard is furnished with milk for its young, by the combination of cartilage with its bile, in the same manner as the cow obtains it by the addition of the secretion from the liver to the starch contained in its food.

We may observe in conclusion, that if Dr. Kemp's plausible theory be substantiated, it will enable us to account for the emaciation and decline of animals deprived of bile, as exemplified in the foregoing experiments of Professor Schwann, and also for the large expenditure of bile in the human body. It is at all events impossible not to be struck with these most ingenious views of Dr. Kemp, or to fail to perceive in the distance conclusions that may become of the highest importance both in physiology and pathology.

ON THE
PATHOLOGY AND TREATMENT OF
OVARIAN DISEASES;
WITH CASES.

By DR. SAMUEL J. JEAFFRESON,
Physician to the Chelsea, Brompton, and Belgrave
Dispensary, &c.

(For the London Medical Gazette.)

[Continued from p. 650.]

THE forms of ovarian disease which most frequently give rise to symptoms connected with pressure upon the rectum or bladder in their earlier stages, and whilst still embedded in the pelvis, are those which are entirely or in the main solid. The first appearance of the tumor above the brim of the pelvis is usually observed on the side of the ovary affected; this may, perhaps, be invariably the case; but certain it is that such fact is frequently overlooked by the patient, especially when there has been no pain or local inconvenience, which has drawn her attention to the disease at this particular stage of its growth. With its increase of bulk, the tumor, whether solid or fluid, at last occupies so large a portion of the abdominal cavity as to prove a source of great and often serious inconvenience. The bowels are commonly rendered sluggish from the pressure made upon them, the stomach irritable, and the digestion impaired; and latterly the

thoracic viscera become so straightened and inconvenienced by the pressure from below upwards, that dyspnœa and orthopnœa supervene frequently to an alarming extent; and the circulation may be embarrassed not merely in consequence of the pressure upon the lungs, but also on the heart and large vessels. Independently of its other mechanical inconveniences, the great weight of the tumor very much exhausts the sufferer, which exhaustion, added to an impaired digestion, and the great demands of this morbid growth upon the system, frequently induces extreme emaciation.

In its earlier stages, the tumor, especially if solid, may, by pressure on the iliac vessels and nerves of one side, produce numbness, pain, cramps, œdema, or other affections of the leg of that side. At all periods of its growth, the tumor, acting as a foreign body on the parts with which it is in contact, may induce inflammation of these parts; the peritoneum being the structure most exposed is of course the part most frequently subjected to inflammation from this cause. The result of such inflammatory action is frequently to induce adhesions between the outer walls of the tumor and the parts with which it is in contact, through the intervention of the coagulable lymph which is thus deposited. It has been suggested by some that such process of inflammation tends rather to control the growth of the ovarian tumor, by binding it down, and Dr. Ramsbotham, in his *Lectures on Midwifery*, has asserted this opinion, and suggested it as the probable rationale of a means of cure presently to be mentioned, which was first recommended by Dr. Hamilton, of Edinburgh. I am not myself inclined to think that such adhesions in any way control the growth of the disease: the constitutional tendency to inflammation, and other circumstances, being, however, equal, I believe the more solid the tumor the more likely is it to induce inflammation and adhesions, as constituting a greater source of mechanical inconvenience and irritation; and as the more solid tumors are for the most part slower in their growth, and much later, if ever, attain the size of the more fluid ones, this circumstance may have given rise to such an opinion.

By irritation or inflammation of the peritoneum probably, in its earlier

stages, and later by such causes combined with pressure on the mesenteric or portal veins, liver, &c., this disease frequently induces more or less ascitic effusion.

Not only may the lining membrane of the diseased mass become inflamed, but the solid tumor itself*. I have already stated my belief that inflammation, or a process short of inflammation, in many instances induces softening, even to fluidity, of the hard and solid portions of the ovarian tumor. In Case No. V. I firmly believe this process to have been the means of cure; but then, as is amply seen in that case, the cure is a desperate one, and attended with the utmost risk to life.

So far, then, both as regards the solid and fluid forms of ovarian disease, their progress has been marked by phenomena chiefly due to their mechanical inconvenience and bulk; and even up to the destruction of life itself they will be found to destroy by single or combined influences due to such causes. Wear and tear, exhaustion, inflammation of vital organs, impeded respiration and circulation, starvation itself—owing to an irritable state of stomach, unable to receive, even could it assimilate, food. To these circumstances may be added the very palpable ones of annihilation of the functions of the organs themselves whose structure is destroyed, and therefore barrenness; and if the disease occur early in life, and affect both ovaries, derangement and ultimate arrest of the menstrual secretion, with the mischief thus entailed upon the whole economy. A subject, however, of great interest, and, in the present day, of great importance, remains to be considered; namely, whether, in the progress of the affection, other and perhaps vital organs are liable to take on a similar form of mor-

* I should be sorry to lay claim to originality for these opinions, which were, I believe, first promulgated by one of my own talented teachers, Dr. Seymour. I may, however, be allowed to state that I arrived at the same opinions from personal observation, and without knowing that they had been entertained by Dr. Seymour or others. It would, perhaps, be well if we were not too eager in our endeavours to be original; for my own part, I consider it no useless or idle matter, by careful observation to confirm what is sound, and to eradicate what is false, in the opinions of those who have gone before us. Many sound practical doctrines have, for want of such confirmation, laid dormant; and many a brilliant but unsound doctrine has for want of wholesome investigation and correction spread its deleterious influence over the opinions and actions of thousands of practitioners.

bid growth to that which has been primarily deposited in the ovaria. It need scarcely be remarked that the decision of this question is of the utmost importance in connection with a subject presently to be treated of; namely, the propriety of removing the diseased ovaria.

That in many instances of post-mortem examination, no similar form of disease should have been observed in other organs, is hardly sufficient evidence upon which to decide this important question; and the more so, perhaps, in that the great bulk of our evidence in all matters of morbid anatomy is derived from our great hospitals. Now comparatively few persons die in our hospitals from ovarian disease in the natural course of things. Some are admitted who, having been retained for a certain length of time, and experienced relief, are discharged to make room for more urgent cases, and lost sight of; others are tapped, and, if relieved, are speedily discharged; but should they die from inflammation, or other cause connected with the tapping, they are examined. In a large portion of these cases the form of the disease is entirely of the fluid character; a form of the disease differing in many essential particulars, and, as I believe, often in its origin (as stated above) from the solid tumor, and therefore out of the field of comparison; or should the tumor have been partially solid and partially fluid, if death has been prematurely induced by accidental cause, it is no more fair to say that the disease is one which is in its nature limited to the ovaria because it is not found elsewhere, than it would be in the case of a post-mortem examination instituted but a few days or weeks after amputation of a scrofulous joint or scirrhus breast, to say, "Oh, the disease is local, because we find no traces of the affection in other organs!" What is it that has rendered the modern surgeon so cautious in removing scrofulous joints and carcinomatous tumors? Not the co-existence of similar forms of disease in other parts at the period of operating, in the discovery of whose presence or absence modern improvements in diagnosis afford him increased facility and certainty, but in the observation that after their removal other and vital organs become but too frequently similarly affected. The cases,

then, upon the post-mortem examinations of which this question of the liability of other organs to become similarly affected would be most certainly decided, are those of long continuance and slow progress to a fatal termination—the very cases, in fact, that are the most rarely witnessed in hospital practice, whence our most extensive researches in morbid anatomy are derived.

It is difficult to bring the mind to regard the large mass of diseased growth witnessed in ovarian disease as entirely a local affection; one is more naturally disposed to look upon it, from analogy, as a disease of constitutional or systemic origin, located in this particular part by some especial determining cause; and if this view of the subject be true, why may not other organs become affected during the progress of the disease, or after its removal by surgical operation? It is, indeed, by no means uncommon to find other organs affected by somewhat similar organic changes, in cases of ovarian tumor. In one out of the two fatal cases cited, the ovary was not the only structure diseased, a great portion of the stomach being found to be involved in a mass of diseased growth, in every respect resembling that of the ovaries themselves. In the other fatal case, the patient was of a strumous diathesis; and portions of the softened structure of the ovary presented those peculiar appearances which are observed in connection with the softening of ordinary strumous glands. In one of the cases, not as yet fatal (the first), the thyroid gland is reported to be greatly enlarged, partially solid, and partially fluid.

The near resemblance of the solid portions of many ovarian tumors to ordinary carcinomatous growths, as respects their appearance and structure, as also the connection of some forms of this disease with a strumous diathesis, as stated by Dr. Copland, have been already adverted to.

Still, it may be said, "if ovarian disease be of constitutional origin, is it not remarkable that, in so many instances, other structures should be found exempt from a similar form of disease; and that the affection should often exist for so long a period without destroying the life of the sufferer?"

To the former objection it may be

answered, "Have we sufficient evidence of the exemption of other parts from similar forms of disease, in the cases of ovarian tumors of long standing?" If such exemption, comparatively speaking, be really true, may not the peculiar nature and position of these organs account in some measure for the fact? Of the purer forms of malignant disease, such as carcinoma, fungus hæmatodes, melanosis, &c., it is worthy of remark, though not readily explained, that diseases like these, coming no doubt out of the whole system, out of the blood in fact, are not often promiscuously deposited in this or that part, as chance may direct them; the absorbent system, but chiefly the absorbent glands, seem to be the parts most prone to promote the fatal termination of these affections, by taking upon themselves a similar form of growth. Is carcinoma or fungus hæmatodes established in the mamma—the lungs, liver, or other organs, may ultimately become the seat of similar disease; but how rarely does this occur till long after the absorbent glands of the axilla, neck, and other adjoining parts, have become affected: whereas, when the internal viscera become first affected, it frequently happens that the absorbent glands are not found to have taken on a similar form of disease, and death has occurred from the organic lesion of a part whose function was of vital import. It would appear as if in all forms of malignant disease the local affection was due to deposits from the blood; whereas the matter thus deposited, if secondarily affecting the system by reabsorption, was reabsorbed not directly into the current of the circulation, as indubitably happens of some poisonous substances, but through the agency of the absorbent vessels and glands.

Now this primary deposit may take place in one part only of the system in the first instance, or in several parts simultaneously; and this is, in fact, nothing more than happens of other depositions not of malignant character—take gout and rheumatism, for example—in which one joint may be affected alone, or several simultaneously. In the case of scrofula, again, a disease but little short of malignant, we find the deposition peculiar to this disease sometimes affecting but one portion only of the body, at others very many parts simultaneously.

From their position, the ovaries are of all organs, perhaps, those the structural changes of which are least liable to contaminate the system through the medium of lymphatic vessels and absorbent glands. There seems, too, some reason to believe, that the establishment of organic changes in one structure, which arise out of constitutional causes, though not affording any *absolute* protection to other parts, yet does induce a tendency of that kind; the deposition once made acting as a nucleus, as it were, for fresh deposit. That such is the case would appear from the fact that the purer forms of malignant growth rarely remain stationary, but almost invariably increase by quicker or slower degrees. When such growths are early removed by surgical operation, it frequently, though not necessarily, happens that little or no trace of the affection reappears in the neighbourhood of the parts first affected, whilst it speedily shows itself in other organs perhaps far removed. In scrofulous affections of the joints, when the cure is effected at the expense of a stiff-joint, I suspect it stands much better than when it is effected by the removal of the limb itself. I suppose that if a gouty man were to lose both his feet, he would not be cured of his malady, but that gouty inflammation and deposition would occur in some other, and perhaps more important part.

Now these observations are irrespective of malignant affections of the ovaries, properly so called; affections in which the local disease, as well as the constitutional states, resemble in every respect malignant disease as established in other structures. There seems no reason why the ovaries should be exempt from organic changes of this character. For myself, however, I must confess that I have rarely, if ever, witnessed a case of ovarian disease, in which both the local appearances, and the general character and symptoms of the affection, exactly corresponded with that of malignant disease. True it is, that the harder forms of ovarian tumor present many of the characters of ordinary carcinomatous tumor; but then the progress of the two affections is usually very different. I suspect true malignant disease of the ovary is of very rare occurrence; nor have many of the published records of such

cases proved at all satisfactory to my mind. I should, however, be sorry to oppose my limited experience to the authority of those who have enjoyed more extensive opportunities of observation. Trusting to the authority of others, we are bound to admit the existence of such form of disease; and what is of greater practical importance (if they do exist), we have no certain means, during its earlier stages, of diagnosing it from the more ordinary cases of ovarian tumor.

It may be proper here to state that Dr. Baron has assumed ovarian as well as many other forms of disease to originate in the formation of hydatids. The ovarian cysts seem to have been pretty generally considered to consist of hydatids by the older physicians, as may be observed by referring to the works of Morgagni, Lieutaud, &c. That hydatids may occasionally occupy this situation is more than probable; such occurrence is, however (as far as my experience goes), very rare. A very small experience in the examination of hydatids will enable the practitioner to distinguish them from the ovarian or other cysts, filled with fluid the product of the secretion of the cysts, which are themselves directly dependent for their growth and existence upon their vascular connection with the parts from which they grow, and to which they become attached.

Diagnosis of Ovarian Disease.

During the various stages of its growth, ovarian disease, whether solid or fluid, is liable to be mistaken for other affections; the subject, therefore, of its diagnosis demands attention.

In its earlier stages, before the tumor becomes visible above the brim of the pelvis, it may (as has been already stated) give rise to constipation or strangury, by pressure on the rectum or neck of the bladder; or it may even induce inflammation of these organs. In such cases it may prove difficult or impossible to discover the ovarian disease to be the cause, and the practitioner will be liable to regard the effects produced as the whole disease. Examinations by the vagina or rectum, excepting under very aggravated circumstances, it would in most cases be indelicate to propose,—nor would they probably be acceded to; or, if permitted, the tumor may be beyond the reach of the finger,

in which case little or no light may be thrown on the affection. Some degree of irregularity, or absolute suppression of the catamenia, particularly if having existed some time previously to the attack in question, may lead the practitioner to suspect some mischief in the ovaries; but then, as such irregularities may exist independently of structural changes of these organs, the opinion amounts in reality to little more than a suspicion. Chronic inflammation or other organic change in the uterus, the retention within it of the menstrual secretion, or retroversion of this organ, may, by giving rise to similar symptoms, be taken for ovarian disease. The diagnosis between these affections can only be cleared up by examinations per vaginam and rectum.

As the disease advances, it may simulate pregnancy; and this not only from the enlargement of the abdomen, but, if both ovaries are diseased, and the tumefaction corresponds in its period and extent with that of pregnancy, the deception will be rendered the more perfect by a correspondent cessation of the catamenia, and sometimes even by enlargement of the breasts and secretion of milk. An instance of this kind is given in Case VI., in which, however, the abdominal enlargement was due, not to the presence of ovarian tumor, but ascites. The deception is still further increased by the delusive sensations of the patient, who frequently declares herself conscious of the movements of the child; and this also was the case (No. VI.) of a woman several years married, and who had borne several children. Professionally speaking, the diagnosis between ovarian disease and pregnancy can rarely be difficult; but, inasmuch as the disease is liable to affect unmarried females, the decision of the question is often one of great delicacy, and of the highest importance, since a mistaken diagnosis may risk the reputation of the patient no less than of the physician, and may involve a whole family in disgrace or misery. An examination per vaginam could scarcely fail to prove to an experienced accoucheur the real nature of the case; but in the instance of single women such could not with propriety be proposed, unless under circumstances of extraordinary difficulty. The practitioner must therefore have recourse to a care-

ful investigation of the patient's history. The mode and situation of the commencing enlargement should be inquired into; the abdomen should be carefully examined as to the present appearance of the tumefaction, and the sensations to which it gives rise on manipulation; the state of the umbilicus should be observed; the cold hand, just removed from a basin of cold water, may be suddenly placed flat upon the abdomen, to ascertain whether any fœtal movements are to be felt; the stethoscope may be used to discover the presence or absence of the circulation of the fœtal heart or placenta. If all these measures fail to afford a satisfactory diagnosis, then, and not till then, in the case of an unmarried person, should the other mode of investigation be instituted. It need hardly be remarked, that in those cases in which motives exist for deception, the practitioner cannot safely rely upon the mere assertions of the patient; the fact of the persistence of the catamenia, and some questions of this character, should therefore be ascertained, if possible, not from the patient herself, but her attendants.

Ovarian tumors, if chiefly solid, will be more readily, if entirely fluid less readily, distinguished from ascites. The history of the case will here afford much information. There may, in all probability, be an entire absence of any evidence of those conditions on which ascites generally depends. The early commencement of the tumefaction may have been distinctly and clearly remarked by the sufferer. Then ascites is usually attended with much more urgent symptoms of constitutional decay than a fluid ovarian tumor of equal standing. As regards the present state of the abdomen, as evinced by local examination, unless the ovarian cyst be unilocular, and the cyst itself very thin, fluctuation will be much less distinct in this than in ascites; or if ovarian, the tumor, though universally fluid, may be distinctly nodulated, its surface presenting to the touch such inequalities as are due to the varied states of distension of the different cysts of which it is composed; if some of these compartments are distinctly hard and solid, the diagnosis will be rendered still more evident. In those instances in which the ovarian cyst is unilocular, and in which the diagnosis between this affec-

tion and ascites is most difficult, I have found the most satisfactory assistance from a plan which I learnt many years ago, at St. George's Hospital, from Dr. Chambers: it consists in placing the patient perfectly flat in bed, and with the head and shoulders as low as possible: in this position, if percussion be used upon the upper portions of the abdomen and around the umbilicus, in ascites it will be found resonant, because the fluid gravitates to the lower parts of the body, whilst the bowels partially filled with air ascend; whilst the percussion of the lower parts of the abdomen, in the line of the ascending and descending colon, will elicit a perfectly dull sound; the reverse of which circumstances occur in ovarian dropsy, which lying before (or in this position rather above), the bowels afford a perfectly dull sound in the umbilical region, whereas the colon, lying below the encysted fluid, affords the usual resonant sound on percussion. This mode of diagnosis may be rendered still further effectual by shifting the position of the patient in various directions, especially when both forms of disease are combined, as is not very unfrequently the case. It will be recollected that the accuracy of this mode of diagnosis was severely tested in Case VI.

Nor are these the only affections with which ovarian tumors are liable to be mistaken. From other abdominal tumors, as of the liver, spleen, pancreas, omentum, mesentery, &c. they are chiefly distinguishable by a careful history into the earlier stages of the case; the concomitant symptoms, and states of general health; the present situation, position, and attachment of the tumors, &c. The mistaken diagnosis of such affections, which was formerly chiefly culpable as evincing a deficiency of professional skill and tact, has become of the more importance latterly, since the revival of an operation which had been previously almost abandoned, for the extirpation of ovarian tumors.

Collections of fæces, or even of flatus, in some portions of the lower bowel, have been occasionally mistaken for ovarian tumors. The position of the colon, in some parts of its course, is liable to occasion such mistakes, which are the more unfortunate, inasmuch as the practitioner may have been induced to abandon the cure of a troublesome

and painful affection, in the idea that it was irremediable; and thus, on the part of the patient, may mental anguish be added to bodily ill. In the instance of solid feculent or other accumulation, a careful inquiry into the history and first origin of the case, with most accurate observation respecting its former and present position, and a careful investigation into the previous state of the bowels, with examination of the present condition of the evacuations, will often be sufficient to lead to an accurate diagnosis, or at least to excite such suspicions of the real nature of the case as to induce the practitioner carefully but steadily to use those means of treatment which are capable of removing the lesser ill. These consist in the steady but active use of purgatives, especially the aloetic, combined with mercurial preparations, scammony, castor oil, oil of turpentine, &c., and the employment of copious enemata. Collections of flatus are more readily recognized by their tympanitic resonance, if the fingers be closely pressed down upon the tumor, and percussion be made upon them with the other hand.

A very abundant deposition of fat in the omentum and abdominal parietes has been occasionally mistaken for ascites or ovarian dropsy. Such an error in diagnosis is not to be treated lightly. A medical man of my acquaintance in this town informed me that a surgeon, since dead, no less celebrated for his professional skill than his excellency of heart, once tapped a patient of his, whose sole affection was a fatty abdomen. The result was fatal. The operation was unfortunately proposed and acceded to, without my friend (who was the ordinary medical attendant) having been consulted with or informed of it: had such step been taken, this disastrous result would have been avoided.

[To be continued.]

ON THE FORMATION OR SECRETION OF CARBON BY ANIMALS.

To the Editor of the Medical Gazette.

SIR,

THE scientific world is at present much occupied with the application of chemistry to animal and vegetable physio-

logy; and it may be interesting to some of your readers to know, that by a few very simple experiments they may satisfy themselves upon that branch of the subject which relates to the formation of carbon by animals.

Suppose an animal, which comprises in its whole system 50 parts by weight of carbon, to be kept for five days, during which it consumes other 50 parts, it is evident that, if during the five days it gives to the atmosphere 60 parts, and at the end of that time it is found to have increased its weight of carbon by 10 parts, there is a positive gain of carbon equivalent to 20 per cent.

The experiment may easily be made upon young small animals. Take two of these so nearly alike, that there can be no material difference in the weight of the carbon they comprise. Kill one of these, and expose it to a temperature not exceeding 220°, for two or three days; it may then be powdered, and by subjecting an average sample to analysis with oxide of copper, the weight of carbon comprised in the entire animal may be determined with the greatest certainty. The other being supplied with food, the weight and chemical constitution of which is ascertained, should be kept in a limited atmosphere, which must be tested and changed every one, two, or three hours*, the increased proportion of carbonic acid of that atmosphere will shew the quantity of carbon given off by the animal in the course of the experiment; and the increase or decrease of carbon in the animal itself may be ascertained in the manner above mentioned.

In this manner I have experimented upon many animals; and without taking account of the carbon which passes off otherwise than by respiration, the result has invariably been a great increase of carbon,—an increase which cannot be accounted for, unless we conclude that carbon is secreted by animals.

Amongst my best experiments are those made with young mice. A healthy young mouse, weighing 200 grains, comprises in its constitution from 25 to 30 grains of carbon; when fed daily with 60 grains of bread moistened with water, containing about 16 grains of carbon, it increases in weight,

* The health of animals appears to be affected by an atmosphere containing more than five per cent. of its volume of carbonic acid.

and imparts to the atmosphere from 20 to 26 grains of carbon, the quantity varying generally with the quietness or the activity of the habits of the animal. A kitten, from six to ten weeks old, when supplied daily with four fluid ounces of skim-milk, containing 66 grains of carbon, will increase in weight, and impart to the atmosphere from 80 to 110 grains of carbon.

Either of these two animals may be kept without food until they give off by respiration a weight of carbon equal to 80 per cent., and retain from 60 to 70 per cent., of that which they comprised at the commencement, shewing that a weight of carbon equal to 40 per cent. has been secreted. The experiment may also be made with birds supplied with little or no food. A tom-tit was placed under experiment without food; the bird was violent and restless during its imprisonment. In sixteen hours it imparted to the atmosphere 65

per cent. of carbon, when it appeared to die of exhaustion, and retained 77 per cent. of the weight of carbon it originally contained; shewing a secretion of carbon in sixteen hours, when under violent exertion, equal to 42 per cent.

On making the carbon in the food, and that in the air respired by a full-grown person, the basis of our calculation, we obtain results which favour the conclusion that carbon is likewise secreted by man. Physiologists estimate the weight of carbon in the air respired by an adult at from 5000 to 6000 grains per diem. I have subjected to analysis many articles of food, and found this weight of carbon far to exceed that in the food consumed by most labouring men, who may be supposed to impart to the atmosphere the greatest weight of carbon. A person eating each day after the following rate will consume 6000 grains of carbon:—

Rump steaks.	1 pound	containing 1050 grains of carbon.
Bread	1½ do.	" 2830 "
Potatoes	½ do.	" 310 "
Porter	2 pints	" 760 "
New milk	2 fl. oz.	" 57 "
Butter	½ ounce	" 320 "
Cheese	1 do.	" 150 "
Sugar	2 do.	" 350 "
Coffee	1 do.	" 96 "
Tea	1 do.	" 80 "

6003

This weight of carbon is not more than is consumed by some persons who are actively employed, but it far exceeds that in the food of our labouring population; and on comparing it with that allowed for each adult in the different workhouses, &c. we have in the dietary of the

	Per Cent. of this 6000.
City of London Union	75
Brentford do.	50
Uxbridge do.	55
Alesford do.	56
Macclesfield do.	44
Westminster New Prison . . .	57
Milbank Penitentiary	80
House of Correction, Clerkenwell	53
Hanwell Lunatic Asylum . . .	75

And if we make the carbon in the food

of some of our agricultural labourers the subject of comparison, we find the deficiency greater than in any of the above mentioned dietaries.

I could add to these many other experiments, which furnish, in my opinion, irresistible evidence of the secretion of carbon by animals. If an animal be kept without change of circumstances, or of diet, except as to the quantity of food, it will be found that the weight of carbon in the air respired does not vary in proportion to that consumed in the shape of food. On the contrary, the deficiency of carbon supplied seems to be met by an extraordinary effort of the animal system, as appears from the following results of accurate observation:—

	In the Food.	In the Air respired.
If an animal in the first 24 hours has a plentiful supply of food, there is	80 grains of carbon.	100
In the next 24 hours a less quantity	70 "	94
" " a sparing do.	60 "	87
" " a small do.	50 "	78
" " a very small do.	40 "	65

But if the animal, instead of having its quantity of food varied, should be sometimes left in a quiescent state, and sometimes excited to great activity, the weight of carbon given off will be found to vary in proportion, within certain limits, to the activity of the habits of the animal, and the exertion called forth.

If the carbon in the food be represented by	100
That given off by an animal of easy habits will be . . .	110
That given off by an animal of active habits will be . .	130
Do. do. when under exertion	140
Do. when under great exertion	150

If the animal be both stinted of food, and excited to great activity, the difference between the carbon comprised in the food and that given off by the animal is as follows :—

In the Food.	Given off.	Difference.
Carbon . 100	120	20
" . 80	105	25
" . 60	90	30
" . 50	85	35

Hence food is a substitute for expenditure of animal strength. To this may be added, that when an animal is distressingly exercised, the weight of carbon in the carbonic acid given off by respiration is at first increased, afterwards gradually diminishes, and becomes much less when the animal is in a state of exhaustion. Rest alone is not then sufficient, but rest and food soon restore the strength of the animal; and with its strength its power of secreting carbon—a power which I conceive to be essential to animal life, and which will probably furnish a solution to some of the most difficult problems of animal physiology, including that of the generation of animal heat,

I am, sir,
Your obedient servant,
ROBERT RIGG.

Greenford, Middlesex,
Aug. 14, 1844.

ON THE ABSURDITIES OF MESMERISM.

To the Editor of the Medical Gazette.

SIR,

I SAT down merely (as I thought and intended) to obtain, through your in-

strumentality, some information about the case of clairvoyance which occurred in the person of Miss M'Avoy, at Liverpool, some quarter of a century ago; and, although recommending silence as the best mode of treating such tomfooleries as mesmerism, &c., I found myself gradually led on to writing what I fear will be too long for publication.

A serious objection to many—even well-informed men—entering gravely upon the investigation of such pretensions as those set up by the phrenomesmerists, is that sooner or later they become bothered, and ultimately may be duped. As Pope says, alluding to the dangerous and contaminating character of vice, that

"Vice is a monster of so frightful mien,
That to be hated needs but to be seen;
Yet, seen too oft—familiar with her face—
We first endure, then pity, then embrace!"

And so do I believe it to be with all follies however great; and, I should say, with mesmerism among the rest. Collusion seems, perhaps, to have been too much talked of, and the real character of delusion not sufficiently insisted on. Men generally would rather be charged with knavery than be considered insane. Insanity, in any form, we naturally shrink from. The charge is easily made,—insinuations, looks, suffice,—and is just as difficult to rebut.

Phreno-mesmerists, in defending themselves from us, stick closely to the collusion part of it; they fight very shy of the other. We have had many of these vagabondizing characters in Newcastle, and bearded them too, publicly in some degree, but chiefly in private. Still, they have pocketed large sums of money; but, like old Shakespeare's "baseless fabric of a vision," they have not left much trace behind. Out of about 120 or 130 medical practitioners, they have only proselytized I think some 3; of whom I shall say nothing.

I am, sir,
Your obedient servant,
M.D.

Aug. 6, 1844.

The "demoniacal mummeries" of mesmerism, as the humiliating, but withal lucrative, exhibitions of Maindoo, Holloway, Louthembourg, and others, were styled (in 1788) by Hannah More—as well as the similar follies of our own day—would perhaps be most suitably treated by silence, since the

consideration of them by men of acknowledged reputation is only calculated to extend and perpetuate such absurdities, by seeming to invest them, in some degree, and for a time at least, with importance and plausibility; by bestowing upon them, so far, the air of something requiring, and likely to repay, the labour and thought of our leading men. To say nothing of the enormous sums of money realized by these vagabonds—the *soi-disants* “lecturers,” and their “subjects” who accompany them,—of whom there can perhaps be only one opinion, how irresistible the temptation thus offered to a Parisian shopkeeper, or a Sheffield poetaster, to obtrude himself on public attention as the fellow-labourer of a man of scientific eminence! How vastly gratifying to the vanity, how exciting to “the love of approbation,” of a sewing girl, or a barber’s apprentice, to be nightly exhibited to a wondering and applauding audience! and, week after week, to figure off as the subject of the so-called “deeply interesting experiments” so eagerly sought after, and, *con amore*, recorded by our newspaper press!

Mesmerism, like the doctrines of many other sects, seems to owe its wonderfully rapid progress, and its singularly enthusiastic reception among the excitable and untutored masses, chiefly to the “soft-sawder” principle. It offers to any and every one, no matter of what age or sex, no matter how ignorant or obscure, the tempting opportunity of becoming, very harmlessly, very conspicuous; it admits the humblest and most insignificant, unrestrictedly for a time, into the society of the proud and lofty; it enables the veriest dunderheads to go hand in hand, as “philosophical inquirers,” (forsooth!) with men of the highest scientific repute! The knowing founders of many of our religious sects were well aware, and as carefully did they avail themselves, of this curious and effective mode of working out their designs; and there is little doubt that quackery, in our own profession, greatly owes its success to the same principle. As when an ignorant self-conceited fellow, swallowing the pills which he has bought on the strength of newspaper puffa, imagines that he has been prescribing for himself (inasmuch as no one else appears to have had to

do with his case!) and forthwith he strenuously recommends his prescription, right and left, with, of course, very little attention to symptoms. It was, in all probability, in much the same manner, and for very similar reasons, that phrenology, or to speak more correctly, cranioscopy, became so rapidly and permanently popular, since, through its magical aid, thousands of incompetent creatures suddenly and most unexpectedly found themselves transmogrified into “moral philosophers!” Talk of reasoning with such happy converts! What! reason them out of their pleasing conceit! No, no!—too well they know that in their case “twere folly to be wise;” their ignorance is blessed; why then disturb them? Mesmerism, however, is not quite so harmless a bauble as is cranioscopy. On perhaps a somewhat similar principle may we account for the remarkable fact that an oral or epistolary discussion—a struggle, as it were, that calls into activity a leading and most universal trait in the human character, viz. the love of power (which, like the desire for knowledge, these would-be mental philosophers, the cranioscopists, have never felt the want of!)—has seldom, if ever, terminated in the conversion of either party—at the time at least. Yet an obstinate bigot may, readily enough, be converted by a book, or by a speaker in a public assembly; provided he get his “new light” unobserved. Your advice, then, seems sound—not to name such a subject as mesmerism to its votaries. Such a delusion it is perhaps best to notice only indirectly, if at all; to exert our energies chiefly or exclusively in preserving the untainted from its influence, which cannot but be injurious. In any discussion on the subject of his delusion, the deluded is often highly ingenious, and in all conscience sufficiently fertile in resources; Xenophon himself might have had many a wrinkle put upon his horn, by our slippery friends the phreno-mesmerists! No less truly than frequently have they hinted to us, that there was “more in heaven and earth” (by which I suppose they must mean in their rum “science,” or in their manner of jockey-ing the same) than we have dreamt of in our philosophy! Keeping, however, his peculiar folly out of view, the phreno-mesmerist may be as candid and

as rational as his neighbour; and on all other occasions, saving always mesmeric discussions of course, he may be sufficiently polite and even-tempered; but upset his conclusions, and expose his "facts"—in short, explode his system, and subject him to ridicule and contempt, and then coolly review your quondam gentleman! The less tenable a man's position is, the more humiliating and insupportable will be his defeat; the reason of so signal a discomfiture is lost sight of, and the victor is blamed for all! The vanquished man, deeply aggrieved, considers himself persecuted; and winds up by charging his honest clear-headed opponent with a gross want of candour, sense, and politeness! Having thus discharged a volley, he turns inwards upon himself, as to the only friend in this world on whom with confidence he can rely; soliloquises perhaps a while; and then, wrapping himself up again in his favourite opinions, he remains a more doggedly obstinate man than before! No feature perhaps in this mesmeric movement has been more remarkable than the settled child-like impatience, the intemperate zeal, nay, downright wrath, with which its advocates (aye, even where these were ministers of the Gospel!) have upheld it; a fact totally inexplicable on the supposition of its being a "science," and but too clearly indicative of its real nature! Yet, blind as an out-and-out phrenomesmerist is to the utterly monstrous and absolutely impossible character of what he (in common with others of his peculiar sect) has espoused, he nevertheless remains "wide awake" to the different delusions of others; a state which he holds in common with monomaniacs, as is exemplified in our various asylums, where may be seen a little caricature of society, each member laughing in his sleeve at all around him, and, in his turn, being laughed at by all; yet each remains happy in his own conceit. These observations may, to many, seem too harsh as applied to the phreno-mesmerists; so they might be considered, if they had been addressed to that body; but, Sir, as your journal is *not* their organ (chosen or self-appointed) we may indulge in the hope that their feelings will in few, if in any, cases be outraged by a perusal of the above remarks—which, however, the recent displays, public and private, seem fully to warrant, and which the

pitiful letter of poor Mons. Marillet most forcibly suggested. Much might probably even yet be done towards recovering such unfortunates, as you properly suggest, by never again thwarting or irritating them, but by letting them have their full swing; their immediate friends, however, would do well to strew their path with such books as Mackay's "Extraordinary Popular Delusions," Hecker's "Epidemics of the Middle Ages," &c. &c. Such works, calmly read, even learnt and digested, with no nasty horrible unbeliever, or quibbling and vexatious opponent present, to disturb the even current of their thoughts, or to chuckle at their want of pig-headed obstinacy, are more likely by far to stem the headlong torrent, or still "the raging tempest" of mesmerism, than all the discussions and investigations that ever have been carried on.

By the way, the preposterous pretensions of Alexis recalled to my memory the very similar case of a Miss M'Avoy, at Liverpool, some twenty or twenty-five years ago; perhaps some of your Liverpool correspondents would oblige us all by a few pages from her "Memoirs"—written, I think, in 4to., no less, by Dr. Renwick, whom she (unaided by mesmerism) succeeded in convincing of downright physical impossibilities. The upshot especially you would do well to record; perhaps it might be quoted, who knows, in the "Mesmerical Times;" and may be it might do good in some quarters. The "mesmerized" of Deleuze, of Dupotet, and others, previously to the "discoveries" in phreno-mesmerism, gave out all kinds of "manifestations," without ever having their "organs excited." But enough of this. I fear that I have already wearied you and your readers even while attempting to take the only (probably) philosophical view of phreno-mesmerism, by regarding it as a comparatively harmless epidemic. About this time last year, Paris was "visited" as London now is: London was then almost undisturbed; so is Paris at present. We certainly do neither dream of, nor experience such things in our philosophy.—Believe, me, Mr. Editor,

Yours truly,

"AN UNBELIEVING SPIRIT."

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Elements of Physiology for the Use of Students, and with particular reference to the wants of Practitioners.
By RUD. WAGNER, M.D. Prof. Comp. Anat. and Physiol. Göttingen, &c. &c. Translated from the German, with Additions, by R. WILLIS, M.D. Memb. Royal Coll. Physicians, Lect. on the Principles and Practice of Medicine, &c. 8vo. pp. viii. and 700. London, 1844. Sherwood, Gilbert, and Piper.

It may be said that there is no want of elementary treatises on physiology, as there are already works of this kind, like that by Professor Müller, of great excellence. But then it must be recollected that this science is eminently progressive, and that, of late years, there has been an accession of new facts and inferences, unexampled since the time of Haller, and perhaps even of Harvey and his immediate successors, Malpighi, Lower, and Borelli. Besides, to the mass of medical men, who have neither time nor opportunity to consult regularly the transactions of learned societies, and the other numerous periodical depositories of physiological research, an occasional new compendium of all that is worth recording, or best established in this branch of knowledge, is absolutely necessary, not only to satisfy a moderate craving for information, but to prevent the reproach of ignorance.

Professor Wagner has been so long known throughout Europe as an accurate observer, and very original inquirer, in the wide field of physiological science, that it is pleasing to see the results of his labours in a systematic shape, and comprising at the same time an account of every thing of importance which has been done by his predecessors and contemporaries. This he has accomplished, as far as the subject of special physiology is concerned, in the present treatise, which is presented to the English reader by a physician whose occupation in practice and teaching have afforded him ample means of becoming acquainted with the wants of practitioners and students, while his knowledge of the additions

which physiology is constantly receiving has enabled him to enrich the work with notes, so as to bring down the information to the very day of publication. In this part of his labour, too, he has judiciously availed himself of the aid of some of his friends, in those branches of the subject to which their attention has been particularly directed, and concerning which their inquiries had previously become of recognised value. And when it is considered that all this has been comprehended in one volume, concisely and clearly, it will be at least allowed that the convenience as well as the instruction of the reader has been carefully had in view—a circumstance which has been neglected in some of the learned and highly valuable works of earlier date.

Professor Wagner divides his treatise into three parts: the first treating of Generation and Development; the second of Nutrition; and the third of Sensation and Motion; thus completing the subject of special physiology. These heads, again, are divided into numerous chapters, each of which is further subdivided in due order, so that the various matters are discussed with admirable method, and the contents of the different sections may be consulted with the utmost facility. The sections treating of the physical and chemical analyses of the blood, and of the lymph and chyle, of the physico-chemical part of digestion, and of the chemical processes of respiration, are by Dr. Julius Vogel.

The part devoted to the subject of generation contains a more complete exposition of this subject than is to be found in any other English work. The male sexual organs and their products are first examined, including a remarkably exact and full account of the spermatozoa in the different orders of the animal kingdom, with a physical and chemical analysis of the spermatic fluid. The figures illustrating the form, size, and development of the spermatozoa, are very numerous, and have evidently been executed with the greatest care. The author regards these curious bodies as essential elements of the seminal fluid, just as the corpuscles are of the blood. He could never satisfy himself that there is any internal organization (like that which exists in the entozoa and infusoria)

in the spermatozoa; and he justly remarks, that the manifold forms which they present must be considered as evidence of so many distinct species, in case their independent animal nature should ever be demonstrated. Viewing these forms, now so clearly proved, it is worth while, as a mere literary curiosity, to refer to the results of the microscopical observations of Mr. Bauer and Sir Everard Home, as related in the fifth volume of Sir Everard's Comparative Anatomy; where he gives a remarkable history of the journeys which he and Mr. Bauer made, and the difficulties they met with in their search for seminal animalcules, with the aid of the best instruments,—but all in vain! Even an examination of the semen of the fallow deer, during two rutting seasons, was equally fruitless. Hence he maintains that there are no such things as seminal animalcules, and that the Leyden student, Ham, who first discovered and shewed them to Leeuwenhoeck, was altogether deceived, and the cause of deception to his successors.

Professor Wagner has given an interesting account of the evolution of the spermatozoa in various vertebrata, and of the enlargement of the testes of birds at the pairing season,—a subject which has since been investigated by Mr. Gulliver*, who has confirmed the accuracy of Professor Wagner's observations, and added some new ones, especially as to the remarkable turgidity and enlargement of the seminal tubes, the attenuation of their coats, and their distension almost to bursting at this period, by the accumulation of seminal cells, the vast increase of minute molecules, and spermatozoa. Well, therefore, might the poet of nature say of the vernal song of birds,

"'Tis love creates their melody, and all
This waste of music is the voice of love."

Mr. Gulliver found the spermatozoa of the camel very nearly resembling in all respects the spermatozoa of the Cervidæ, although it will be recollected that the Camelidæ present the curious anomaly, among mammals, of oval blood-discs. The spermatozoa of mammalia, he observed, were not at all affected by various re-agents, as acetic

and several other acids, which quickly act on most animal matters; yet the spiral spermatozoa of birds were immediately destroyed by the vegetable acids. This curious observation well shows the justice of Professor Wagner's remark, in speaking of the chemical nature of the spermatic fluid, that microscopical analysis must henceforth go hand in hand with that which is purely chemical. Having mentioned the spermatozoa of the Cervidæ, we may just add, that these very objects, which seem to have caused so much trouble to Sir Everard Home, were always found by Mr. Gulliver in the fallow deer at Windsor, both during the rut and at other times.

Professor Wagner next proceeds to a consideration of the germ-preparing organs in the female, which, with many other allied subjects, must be consulted in his pages. The history of the incubated egg is very well told; and then we come to the account of the development of the human embryo, with supplements from the history of the embryo of lower mammalia. And on this subject it is gratifying to see that the translator has done justice to the claims of Mr. Wharton Jones, of whom it is remarked, that he was, beyond all doubt, the discoverer, independently, but contemporaneously with others, of the germinal vesicle and spot in the ovum of man and mammiferous animals. By what strange error Mr. Jones's paper was not printed in the Philosophical Transactions, after it had been read at the Royal Society, is a subject deserving of some inquiry, especially as it is well known that he was the original interpreter in England of the important discovery of Baer, and fairly confuted him on the question as to the Graafian vesicle at large of the mammal being held as corresponding to the vitellus, with its contents, in the bird.

Professor Wagner next treats of the development of the various tissues; and here, besides his own observations, we have those of Schwann, and of Valentin, in two distinct papers, drawn up by the authors themselves specially for this work,—a fact which ought to be sufficient to induce every physiological student to possess himself of treasures of which he cannot obtain elsewhere an English version in such an authentic form, and which have the rare

* Proceedings Zoological Society, July 26, 1842; and April 11, 1843.

merit, at least among discoverers, of great clearness in a moderate compass.

Professor Wagner proceeds in the next place to treat of Nutrition, beginning with the blood, which may be assumed as the centre of the process. The microscopical analysis which he has given of the blood corpuscles has never been equalled in any systematic work before published; and the translator has enriched it most materially from the numerous observations of Mr. Gulliver. On the long contested question as to the nucleus in the blood discs of mammals, these two observers seem to agree that it does not exist,—at least that these discs have no nucleus like that found in the lower vertebrata.

By this statement it is not intended to deny that the corpuscles of mammalia are destitute of any central matter, for Mr. Gulliver depicts this part of the corpuscle, which remains after repeated ablutions with water, as very thin and diaphanous, and about two-thirds the size of the fresh and unaltered disc. This central part, therefore, has no resemblance whatever to the nucleus of the blood disc of any vertebrate oviparous animal. According to Mr. Gulliver, even the blood discs of the camels, which are of an oval shape, correspond in structure with the blood discs of other mammals.

The observations of Henle are also to the effect that the blood discs of mammals are mostly destitute of any regular nucleus. But both Professor Wagner and Mr. Gulliver prove the existence of a most substantial nucleus in the blood corpuscles of very young mammiferous embryos,—an interesting fact, showing that what belongs to the blood of the mammal only for a short time during intra-uterine life, is a permanent character in the blood of the oviparous vertebrate animal.

The globules of the blood, commonly known in this country as the colourless or white globules, the author describes as the second order of solid elements in this fluid. He, like Hewson and Müller, regards them as lymph globules, and shows, from some interesting and new experiments, that they are always very numerous, if not most plentiful, in well-fed animals. In frogs these globules were seen by him much more abundantly in August than in February. The globules found in lymph are said to bear a strong resem-

blance to the pale globules of the blood; to which it is added by Mr. Gulliver, that the latter are rather larger and more regularly and distinctly nucleated than the former. Professor Wagner agrees with Nasse, Henle, and others, that an envelope may be often seen forming around these lymph globules, which is interpreted as their transition state towards the common red blood corpuscle. The chyle and lymph globules are stated to swim in a fluid that is comparable to the plasma or liquor sanguinis, which is no subject for further microscopical inquiries—a remark which the translator very properly objects to, since the microscopic fibrils in the chyle have been distinctly figured by Mr. Gulliver (Gerber's Anatomy, fig. 281), who also shows that the base of the rich chyle during digestion is formed of very equal sized and extremely minute molecules, which appear to be of a fatty nature (loc. cit., note, p. 56, and App., p. 89). The observation is interesting, because the researches of Acherson, Henle, and Dr. Davy, have shown it to be probable that the elementary granules or nucleoli of cells are constantly allied in chemical character to oleine; and as Dumas has declared that animals only derive fat from vegetables, being incapable of converting starch or any other vegetable matter into fat, it may justly be asked whence comes the molecular base of the chyle, and the larger fatty globules, which Mr. Gulliver has seen in the horse? In the account of the blood generally there is a vast quantity of information which cannot be considered here. The translator has rightly insisted on the just claims of our eminent countryman William Hewson, and has added much additional matter from the very original and important researches of John Davy.

Passing over the account of the vascular system in the various organized beings, from vegetables to man, and the subjects of digestion, respiration, secretion, absorption, and the more intimate processes of nutrition, sections to each and all of which the translator has added many original and practical observations of great interest, both to the physician and the phrenologist, we come to the Third Part, which comprises the history of Sensation and Motion, with all the parts concerned therein. But

here, though we see that there is much matter well calculated to engage attention, we also see that the limits commonly allowed to a notice of this kind have already been exceeded. It is not within the scope of the *MEDICAL GAZETTE* to give a regular abstract of the multifarious objects, extending over the whole domain, of a systematic work on physiology; therefore, nothing more than a glance at some of the interesting matters with which Professor Wagner's treatise abounds has been attempted, and even this has led to a more lengthy notice than could have been allowed for an ordinary publication. Here, therefore, we must pause, and refer the reader again to the work itself; yet the last note, exhibiting a tabular view of the result of several hundred observations on the weight of the human brain, by the excellent resident physician to the St. Marylebone Infirmary, Dr. Boyd, must not be passed over. He shows that the weight of this organ increases from the age of ten to forty years, and soon afterwards begins to diminish. When, therefore, the concurrent observations of the late Dr. Sims are considered, the prevalent error that a child of eight years of age has as large a brain as a full-grown person, must be discarded; while it appears that the greatest size, or at least weight of the brain, is generally connected with the greatest vigour of the mental faculties. To prove the difference of size, however, without the possibility of any further doubt, observations on the specific gravity of the brain at different ages should be made; and these are yet wanting to physiological science.

The woodcuts, too, with which the editor has so profusely illustrated the work, require especial notice. They are chiefly derived from the *Icones Physiologicæ* of Professor Wagner, but often, also, from original sources.

The execution of the cuts is highly creditable to Mr. Vasey; for, with a few exceptions, such as figure 140, they are really excellent, and the best examples of the kind with which any physiological treatise had before been so liberally adorned.

When we consider the wretched affectation of some English anatomists in explaining all their figures by Greek letters, and in adopting foreign standards of measurement instead of

English ones, for the microscope—and that, too, while our continental neighbours, in quoting our own works, take especial care to render our measures, either of heat or size, into the standards of their country—it is to be regretted that the editor of Wagner, in escaping some of these sins, had yet not given his measurements in vulgar fractions of an English inch. It is true that a very easy rule is given by which Paris lines may be turned into English measure; and it is also true that very excellent tables of contents precede the work, though this is scarcely a sufficient reason for the omission of an index.

It does not seem too late to rectify some, at least, of these objections; they would, indeed, be of comparatively little moment, were it not for the passing worth of the English version of Professor Wagner's *Physiology*, which is certainly the most original, exact, and comprehensive treatise on the subject which has ever appeared, within nearly the same size, in this or any other country.

MEDICAL GAZETTE.

Friday, August 23, 1844.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE NEW MEDICAL BILL—No. II.

SHALL THE MEDICAL PROFESSION BE OPEN TO ALL AND SUNDRY, LETTERED AND UNLETTERED, COMPETENT AND INCOMPETENT, CHEMIST AND DRUGGIST, QUACK AND IMPOSTOR, OR SHALL IT BE LIMITED TO THE EDUCATED PHYSICIAN AND SURGEON?

IN our last number we fixed upon what we regarded as the cardinal defect in the proposed Medical Profession Bill, viz. its silence in regard to all manner of quacks and ignorant and unlicensed practitioners. We see no reason to depart from aught we have there advanced: it may not be easy, it may not be possible, wholly to prevent quackery and incompetency from meddling with the practice of medicine; but the law ought to shew its abhorrence of quackery, and to set its face against

incompetency in the exercise of the most difficult art that engages the ingenuity of man, by decidedly and distinctly proclaiming that it would use every available means, even to the *peine forte et dure* of incarceration and fine, in order to protect the community against malpractice in the art medical. It has not yet been found possible to prevent robbery, or murder, or rape, or wilful fire-raising, or defamation, or any other of the deadly crimes; yet who would be so mad as to propose repealing the whole of the statutes against theft and murder, rape and arson, &c. &c.? To pass the Medical Bill as it now stands would be virtually to throw three-fourths of the medical practice of England into the hands of chemists and druggists, who, merely because they deal in the articles that are used by the physician and surgeon, and compound according to their prescriptions, even by educated persons are all but universally regarded as skilled of course in the knowledge and treatment of diseases.

Strange to say, a tender regard—we say an over tender regard—to the interests of this class of shopkeepers, is made a principal difficulty with some persons in regard to the introduction of any clause into the Medical Bill affecting incompetent persons. The mischief that is done at the present day by the class of tradesmen in question, is, however, sufficient of itself, we conceive, to call for the interference of the legislature. The ignorant public do not know that they might as well apply to the green-grocer, because he deals in thyme, and marjoram, and mustard, in case of the illness of a child or other near relative, as to the man at the corner of the street with the red bottles in his window, because he has rhubarb and senna and cream of tartar for sale. Yet do the ignorant public and the poor every day pay

heavy penalties for their misplaced confidence in this quarter. The man with the red bottles nine times in ten will obey the summons ignorantly given, and utterly without medical knowledge, knowing nothing of the state of things for which he is prescribing; if perchance he be acquainted with the action of the medicines he orders, he suffers disease that might have been nipped in the bud to acquire a virulence in its future stages that bids defiance to the best directed efforts of consummate skill. It is unknown what numbers die in our large manufacturing towns, who have never had any medical attendance at all; we have seen documents in the hands of the active head of one of our great public offices, which assure us that a very considerable proportion—fully one-third—especially of the children of the poor who die in Manchester, have had no medical assistance whatsoever: they have been attended by a neighbouring chemist and druggist, who had unquestionably as well have staid away, if his ability to minister to any one symptom of the least significance be considered. This is a state of things which we say of itself calls for legislative interference; and unless the party in power be of that school of political economists who have no bowels of compassion for the sick and the poor, and who regard a growing population as a growing evil, we do not see how they can refuse it. He who is the cause of one life being lost by his interference, that might have been saved but for him, is scarcely less guilty, morally speaking, than the wilful exhibitor of the pennyworth of ratsbane.

We cannot for our soul see the chemist and druggist in any other light than as a vender of the substances used by practitioners of medicine—as the trader who supplies the artist or handicraftsman with his materials. The

ironmonger may be a good judge of a file or a nail, yet is he not either watch-maker, locksmith, or carpenter; a colourman may be a good judge of ultramarine and carmine, and nut oil and mastic varnish, &c. yet no painter. Our friend Mr., Sharpset is a good cutler, and deals in knives and tenaculums, and gorgets and forceps; but is he therefore to be held competent to take off a leg, or to cut for the stone? No more is the dealer in rhubarb and scammony, blue pill and tartar emetic, to be regarded as necessarily familiar with their use in disease, or acquainted with the circumstances which indicate their exhibition. More than this, if by dint of handling and mixing medicines he thinks that he acquires any knowledge of the natural and disordered functions of the human body, and of the agencies which influence and restore them, the law must assure him that he is mistaken—that he is incompetent to interfere under such circumstances; that if he does, he is tampering with the life of a fellow creature, and will be held responsible for the consequences.

That the functions of the chemist and druggist are one, and those of the practitioner another, seems proven by the fact that the most respectable chemists and druggists decline prescribing.

In Conduit Street, for instance, we reckon three first-rate establishments, one after another, where medicines of the best quality are to be obtained, but neither Messrs. Godfrey nor Bullock, nor Fisher and Toller, would visit a man affected with fever, or a child labouring under measles, nor a man with a broken leg, nor a woman in her confinement. These respectable men confine themselves to their own province, and wish not to meddle with the practice of medicine. What they do in their several instances should be made imperative generally. Every day, every hour,

satisfies us more and more of the necessity of having well-educated and high-principled men as guardians of the public health. Let the reader look at our next article, and see how ignorance and incompetence lend themselves to the slaughter of innocent children; this could not have gone on long un denounced, had the practitioners in every instance been men of the education and character which the vast majority of members of the College of Surgeons and licentiates of Apothecaries' Society boast. Mr. Belaney would have buried his wife snugly in a *common* grave, a bricked one not being to be got ready with despatch commensurate with his impatience to see his spouse entombed, without the interference of Mr. Garrett, the intelligent general practitioner who was the cause of the coroner's inquest being held at all, and of Mr. Belaney's being now committed to Newgate, charged with the wilful murder of his wife. Every day, in short, is pregnant with a new instance in which society benefits by having men of education and consideration in the world for its medical attendants.

It is absurd, it is dangerous, then, to say that every man is to be left at liberty to practise physic and surgery, and that the law can do nothing to prevent him. Does the government allow every man who so inclines to brew beer and distil spirits, or to retail either or both of these poisons? By no means; it requires every man who meddles with the destructive handicraft and traffic to be regularly licensed; and so stringent and effectual are the laws on the subject, that there are probably not half a dozen illicit stills of the smallest size in England at this hour, and not one unlicensed dealer in home-made fermented and spirituous liquors. The law can do everything, as it is bound to do everything, to put a stop to incompetent

practitioners of medicine among the poor and the ignorant. We are the more urgent upon this matter, because there is a decided tendency at this moment to supplant the old apothecary, who was always held to have had some medical education, by the chemist and druggist, who avowedly has had none. What will the public gain by the suppression of the Society of Apothecaries as a medical body, if it have the Pharmaceutical Society, or an unattached corps, of chemists and druggists fastened on its shoulders? Less than nothing; indeed a great loss. The Court of the Society of Apothecaries are now men of comparatively liberal education; if they have less than seems desirable even to themselves, they have long striven well and zealously to secure the blessings of higher attainments to their younger members or licentiates. We are for a divorce between the profession of medicine and the traffic in drugs; and therefore have we treated the Court of the Society of Apothecaries with less of consideration with our pen than we feel for its members in our heart. The course of education prescribed by the Apothecaries' Society would doubtless have been much better even than it is, had they been alone and unfettered by the presence of the College of Surgeons. They have apparently calculated, however, that the deficiencies in their curriculum were in great part supplied by that required at the College of Surgeons; and this in some degree it is in fact, for the great majority of the licentiates of Apothecaries' Hall are also members of the College of Surgeons. Our war has been wholly with the trading element in the constitution of the company, or as it is now designated, doubtless with the object of keeping as much as possible out of sight,—the *Society of Apothecaries*, not with the respectable men who are its members or licentiates;

these constitute probably three-fifths or more of the practitioners of medicine in England, and with their present acquirements are guardians of the poor, especially in times of sickness, whose competency and efficiency cannot be questioned. It would be a grievous matter indeed were this educated body of men to be supplanted in the next generation by a body altogether without education. But Hope was at the bottom of Pandora's box, and we do not despair of seeing Sir James Graham and the Ministry yield to what is reasonable on a matter of so much moment to the community as is the Medical Profession Bill, however little store honourable members of the House of Commons appear to set by it, when they listen to its introduction in such scanty members as two under the dozen—we are compelled by our feelings, here to speak by circumlocution.

The question of suppressing quackery and interfering with incompetency in the practice of medicine, is often treated as if it were personal to the members of the medical profession; as if they were the parties peculiarly interested in the suppression of quackery, &c. This is the view taken by our esteemed correspondent *Scrutator*, whose excellent letter—though we differ from him—is published in this day's *GAZETTE*.

We, for our part, repudiate this view of the matter entirely; we, and the portion of the profession we mainly represent, care not one rush for protection; we do not seek it; in so far as *our interests* are concerned, we would rather be without it. It is in behalf of the community that we raise our voice, not in behalf of ourselves.

INFLUENCE OF BURYING-CLUBS IN AUGMENTING THE MORTALITY:

PREMIUMS ON THE DEATH OF CHILDREN.

IN the evidence of one of the physicians examined before the Commissioners of

Inquiry into the state of large towns, &c., whose first Report has just appeared, we observe these words: "I used often to observe great apathy in a certain class about the death of their children. They did not seem to look on the death of the young as the great evil which it is commonly regarded; they said, 'God took care of young children who died; that their death did not matter much; that life was full of hardships and misery, and that the child was provided for when it died.'" This feeling I found to be rather common (3313, p. 203). The picture here presented is true to nature so far as it goes; but the shades in which it must be finished, we regret to say, are of a much deeper grain than those yet laid on. There is not merely indifference among the labouring population of England in regard to the death of their children; in some places there is a positive premium upon the event, and that to such an amount that instead of dog-cart and dog-stealers' bills, and chimney-sweepers' bills, and black-legs' bills, we shall, next session of Parliament, have to get some benevolent legislator to introduce a bill to prevent English men and English women from being accessory, in cold blood, to the destruction of their own offspring!

The new sacrifice to Moloch is perpetrated in this way: soon after a child is born, it is entered on the books of as many *burying-clubs* as the parents can command funds to pay for. The sum subscribed to each is but a few pence, or even half-pence, weekly; so that parties being in full employment can sometimes afford to have the name on the register of ten or a dozen of these societies. And the investment may always be made a profitable one: the hapless child has *but to be killed* by exposure, by neglect and worse treatment, to give these unnatural parents a

claim upon the several societies of which they have enrolled their infant a member, to the extent in all, perhaps, of £30, £40, and even £50!

We feel the hot blood rising to our cheek, as the outward sense follows the pen that is fixing indelibly such statements as these, which will soon be before the public in all their revolting details, authenticated by the Commission whose first report is referred to above.

What comment shall we make, what comment *can* be made, upon a state of society so horrible—a state of society in which one of the first and most powerful impulses of the human heart is set at nought? Tigers and wolves give suck, and laying their savage natures by, tenderly wait upon and cherish their young. Man and woman, made more than wolf or tiger by force of circumstances, beget children in the prospect of deriving pecuniary advantage from their death!

The difficulty of living, the recklessness that is engendered by the pressure of vice and misery, and the daily and familiar contact with them, lead men first to despise the laws of God, which are also those of nature, and then to defy the laws of man—to set fire to the ricks that contain the harvests which their own hands have toiled for and gathered, and so to destroy in an hour the bounty of a year,—to smother natural affection in their hearts, and doom their own flesh and blood to premature death, that they may have a fuller meal and a draught of beer the more! Great God! is it not horrible! What may be done to abate the fast accumulating load of guilt and infamy under which we must needs bewhelmed if we sit supine? We put it to our brethren to meditate this subject, and to use the light and information they so commonly possess for the illumina-

tion of those among our men of rank and influence with whom, in the course of the holidays, so many of them are brought into contact. Let them remind these our leaders that the time is not long gone by, when defective legislation raised the price of a perishable human carcase to such a height, that it became a temptation to commit murder; and that at one time subjects were selected for the dissecting room in the streets, just as sheep and oxen are selected for the shambles in the fields.

—

HOW WILL THE INTERESTS OF THOSE WHO ARE NOW ABOUT TO ENTER ON THE STUDY OF MEDICINE BE AFFECTED BY THE PROPOSED MEDICAL PROFESSION BILL?

WE have had various queries addressed to us to the above purport and effect. Our answer may be brief: In the sense in which the queries were addressed, nascent interests will in nowise be affected by it, should it become law,—the bill cannot be made retrospective; they who commence their medical studies now will be receivable into the profession under the conditions at present required.

There is another view of the subject, however, which may merit consideration. Would it be worth any man's while to enter upon a laborious and expensive course of preparation for a profession which it is proposed henceforth to throw open to all without any study whatsoever?—a profession in which the educated man would be liable to be jostled by the uneducated man; in which the licentiate in medicine and surgery might find himself disputing the ground with the chemist and druggist, the herbalist and cow-leech, the water-doctor (in more senses than one), the bone-setter, the travelling tooth-drawer, and the mountebank of the fair?

Verily, we opine that it would not. We should only venture to recommend him to do so on the score of the conviction which still gains strength in our mind, that the profession of medicine will continue to be recognized in law as one whose members are distinguished by the extent and variety of their accomplishments; and that the public, as they are already protected against ash and sloe leaves under the title of tea, against putrid fish, unsound meat, &c., will be further protected against quacksalving and incompetency in every shape, by a brief and simple statute, which shall make it penal in any but a regularly educated man, who has given evidence of his general fitness for the duty, to practise medicine in any one of its departments.

—

THE MEDICAL PROFESSION BILL.

To the Editor of the Medical Gazette.

SIR,

As you have not declared war against Sir James Graham's Medical Bill, I trust that you will permit me to offer a few remarks upon some parts of it, with the view of pointing out to the profession to what extent it may really affect their interests. I am the more induced to take this liberty with my medical brethren, inasmuch as I have already given an "Exposition" of those laws which the present bill proposes to repeal.*

That I may not interfere with your own lucubrations, as I see that you purpose going over the whole of the bill, I shall at this time confine myself to that remarkable feature of it which you have already reviewed, viz. the abrogation of the Apothecaries' and all other acts bearing upon the exercise of the healing art, without the substitution of any clause against the practice of medicine or surgery by unqualified persons. In what I am about to say, I would premise that the introduction of a prohibitory clause against unlicensed practitioners need not affect the principle of the rest of the bill; therefore,

* *Lancet*, vol. 1 and 2 for 1843.

those who are in favour of such a clause may urge their views without denouncing the whole bill.

But let us first consider what the Apothecaries' Act (55 Geo. III.) has done in the way of preventing quackery; and in the second place, what probability there is that a prohibitory clause in the present bill would afford any protection to licensed practitioners.

I will first call the attention of my brethren to a "great fact," namely, that at present, any person, however ignorant, even who may not know the alphabet, may get the word "surgeon" engraved or painted on, or over, his door: may bleed; may set a limb, or pretend to do so; may prescribe and dispense medicine for the fever that may arise from any accident, or for any surgical disease whatever; may charge for doing so; may recover the amount in a court of law, as legally, to all intents and purposes, as any the most eminent surgeon may do. Now, under the proposed bill, not only will such a person not be able to recover any charge in a court of law, but moreover, any one pretending to be a surgeon, and who is not, is liable to fine and imprisonment. The clause states, "that every unregistered person who shall wilfully and falsely pretend to be, or take or use any name or title implying that he is registered under this act, shall be deemed guilty of a misdemeanor," &c. Of course, no one can be registered who is not a qualified practitioner. Is not this step, in the right direction?

The Apothecaries' Act relates to England and Wales only: any one may practise in her Majesty's colonies without being qualified under the act; or may hold any public appointments without incurring the risk of a penalty.

It is true that the present bill does not go so far as to attach a penalty to those who may hereafter choose to give advice and medicine, but they will not dare to call themselves physicians, or surgeons, or licentiates; nor will they be eligible to any public appointments. Surely this is an improvement upon the present system.

The inconsistency attending the present laws with regard to licensing practitioners is well known. Not only is an English licentiate not entitled to practice in Scotland or Ireland, and *vice versa*, but the London license

of the English College of Physicians does not give its possessor the right to practise beyond the distance of seven miles round the metropolis; nor does the country license, on the other hand, confer the right of prescribing in London, or within seven miles of the same. The great majority of the physicians to our provincial hospitals and infirmaries, as well as those who practise privately, are illegal practitioners. As the law stands, no person has a right to practise as a physician in England unless he hold the license of the College of Physicians of London, or a degree from Oxford or Cambridge. These inconsistencies will be entirely remedied under the present bill, without materially affecting the interests of any of the bodies which now confer licenses; and without at all interfering with the interests of the present race of practitioners, who will be legalized under the bill by merely causing their names to be registered. This circumstance must prove a very great boon to the Scotch graduates, who form the great bulk of our provincial physicians; for, although the College has not interfered with them of late years, still it is not so pleasant to reflect that they are permitted to practise upon sufferance, as it would be to feel that they are doing that only which they have a right to do.

Now, what has the Apothecaries' Act done towards the prevention of quackery and unlicensed practice? In speaking of the operation of that act, I do not in any way intend to cast blame upon the Apothecaries' Company. The faults are in the act itself, and not in those who have been charged with its administration.

I am not acquainted with the exact number of prosecutions of unlicensed practitioners instituted under the act, but I know that it has been very small. It is also well known that some of these, if not the majority of them, were against members of the College of Surgeons. Even for this I do not blame the Company, because if informations were laid before them against such persons they could not well avoid prosecuting. The act has been in operation just nine-and-twenty years: about a dozen, perhaps, unlicensed practitioners have been prosecuted under it: quackery and unlicensed practice are as rife as ever both in town and

country: that is the true state of the case.

The Apothecaries' Act has been thus far essentially useful in improving the education of the general practitioner. This is a fact which no one can reasonably dispute. But so far as the prevention of quackery is concerned, if it were ever intended to interfere with quackery, it has proved a signal failure. The wording of the act in relation to unqualified practitioners is stringent enough: how is it, then, that it has failed in accomplishing its object? How was it that the College of Physicians, for centuries, armed with the most stringent acts of parliament, entirely failed in accomplishing the same object in the metropolis? The truth is, that the object cannot be accomplished by the power of an act of parliament. The history of centuries proves that to be the case.

All the good points of the Apothecaries' Act are embraced in Sir James Graham's bill. The rest of it has outlived its day. It has been useful in its time; but the same usefulness may be continued in a better, more simple, and by far more respectable way as regards the profession.

In legislating for ourselves, we are bound to take into consideration the interests of others. It is evident that quackery has been legalized by the granting of patents for the sale of nostrums. There is a very large capital invested in such property in this country, and it is difficult to conceive how quackery can be eradicated while patent medicines are allowed to be sold. If we defer our Medical Reform until the time arrive when secret nostrums are prohibited from being sold, we shall certainly wait until the day of doom, so far as we are concerned.

There is also another class to be considered, who have maintained a certain privilege for a considerable number of years, namely, the retail chemists and druggists. These persons claim the right of giving "advice over the counter," and have exercised it in spite of the Apothecaries' Act. The present Bill will neither increase nor diminish their right in that respect; but a prohibitory clause, if acted upon, would affect their interests in a way to render it almost impossible for them to carry on their trade. This class, therefore—a powerful one—would naturally and

justly raise a cry against a bill containing such a clause.

But the worst thing of all would be, and the most detrimental to the interest of the profession, that the public generally would cry out tyranny against us, if we attempted to enforce the provision of a prohibitory clause. Such a clause, unless rigidly put into execution, would be worse than useless, because the profession would have all the discredit of it, without any benefit from it. The public are jealous of having their ancient privilege of being cheated touched. They may be considered foolish for being so, but the remark is not the less true for that. They think that they "have a right to do as they like with their own" health. The poor will go into Mr. A. or Mr. B.'s shop for two pennyworth of his aperient or his antibilious pills, in spite of all acts of parliament; and the young gentleman, after passing, feeling the claret or gintwist of the previous evening lying rather uneasy on his stomach, will turn in for a dose of Mr. H.'s prime bitters. Can you prevent such a practice by an act of parliament? Both rich and poor swarm after homœopaths, hydro-pathists, mesmerists, and all descriptions of quacks. The question is not whether they act wisely in doing so, but whether you can do any good by attempting to prevent them by the enforcement of a law; whether, by endeavouring to force the provisions of such a law, we should not place ourselves in a much worse position, by having the public cry against us.

It must also be taken into consideration, that juries would not convict under an obnoxious law, however clear the evidence; so that it soon would become a dead letter, as the Apothecaries' Act did so far as the prevention of quackery is concerned.

In truth, notwithstanding the great improvements of modern times, medicine is still a "conjectural art" to a great extent. If a patient, whether poor or rich, has given eminent, regular, and licensed practitioners every opportunity of doing him good, and they fail to do so, it would be hard to deprive him of the hope and consolation of sniffing a millionth part of a grain of ipecacuanha into his nose, or to twist a wet sheet round his body, or to have a certain number of unmeaning figures cut in the air before his face by the passes of the mesmeriser's hands.

718 PARLIAMENTARY PAPERS RELATIVE TO THE COLLEGE OF SURGEONS.

We even find not a few men connected with our profession who, at a former period, bore some reputation, take up with these crotchets. Whether such men, or such professors in general, are knaves or fools, or either, or neither, is not the question at present: they at any rate prove that the non-medical public are not the only promoters and encouragers of dupes and victims of quackery.

The provisions of the new bill appear to me calculated to do much more good towards the discouragement of illegal practice than a direct prohibitory clause would be. The facts that no person will be qualified to hold any public appointment without being registered (which, of course, is the proof of his qualification); that his certificates or evidence in courts of law shall not be received as those of a medical practitioner; that no person not registered shall be entitled to recover at law any charges for attendance or medicine, either in medical or surgical cases—all these form as strong a defence against the intrusion of interlopers into our profession, as the public are at present ready to concede to us.

I conclude by observing, that the insertion or non-insertion of a prohibitory clause need not invalidate the rest of the bill. I have stated the reasons which occurred to me against the expediency of such a provision; others may have stronger reasons to adduce in its favour; but the profession may rest assured of one thing, if they reject the present measure, it will be many a day before they will have the like of it offered to them again.

I am, sir,

Your obedient servant,
SCRUTATOR.

August 18, 1844.

PARLIAMENTARY PAPERS

RELATIVE TO THE

COLLEGE OF SURGEONS,

viz.

COPIES OF TWO LETTERS, from Sir James M'Grigor and Sir William Burnett, on the Nomination of a further number of Medical Officers in the Army and Navy to the Fellowship of the College of Surgeons; together with the Observations of the Council explaining the Principles on which they proceed in the preparation of the Schedule of Fellows of the Royal College of Surgeons.

COPY OF A LETTER addressed, on the 31st day of July, by the President of the College of Surgeons, to the Secretary of State for the Home Department, on the subject of the CHARTER lately granted by Her Majesty to the Royal College of Surgeons of England, together with its Enclosure.

[Ordered by the HOUSE OF COMMONS to be printed, 6 August, 1844.]

(From SIR JAMES M'GRIGOR, Bart.)

To the President and Council of the Royal College of Surgeons, &c. Lincoln's-Inn Fields.

Army Medical Department,
27 February, 1844.

Gentlemen,—I have the honour to submit to you the names of 75 medical officers of the army, whom I beg to transmit to you as in my opinion worthy of the honour of "Fellows of the Royal College of Surgeons of England," and whom I recommend accordingly for the approval of the Council.

I have, &c.

(Signed) J. M'GRIGOR,
Director-General of the Army
Medical Department.

(Here follows a list of the names.)

(From SIR WILLIAM BURNETT.)

To the President, Vice-Presidents, and Council of the Royal College of Surgeons of England.

Department of the Inspector-General
of Naval Hospitals and Fleets,
Admiralty, 24 Feb. 1844.

Gentlemen,—I observe, by the list of fellows lately published, to the number of 300, that the Council of the Royal College of Surgeons of England have departed from their original intention, as communicated by Mr. Guthrie, the late President, who, by desire of the Council, addressed a letter to me, explaining privately its objects, and requesting the names of the medical officers of the navy of the inspectorial rank, and who might be members of the College, to be associated as fellows with the surgeons and assistant-surgeons of hospitals, and the teachers of anatomy and surgery throughout the country, together with the older members of the profession not practising pharmacy.

That the Council has departed from its original intention appears by its having placed on its list of Fellows many young gentlemen, members of as late a date as 1837, and several others now practising as apothecaries; whilst it has totally overlooked all the surgeons of the navy, many of whom are very distinguished officers and members of the profession. This having been done without any reference to me, and being at variance with the practice observed in the case of those bearing the rank of inspectors and deputy-inspectors, whose names I beg to insert, viz. :—

Henry Parkin, late Marine Barracks, Woolwich; William Rae, now Melville Hospital, Chatham; William Conborough Watt, now Naval Hospital, Malta; Robert Armstrong, now Naval Hospital, Plymouth: these gentlemen all holding the rank of deputy-inspector of naval hospitals and fleets.

Under these circumstances, I think it but an act of justice to the naval medical service to enclose a list of surgeons of the navy, all of whom are highly deserving officers, and to request that the names of these gentlemen may be placed on the second list of fellows, to be made out before the expiration of one year from the date of the charter, viz. 14th September, 1843, as directed by clause 4 of the charter in question; observing that there are many other surgeons, who no doubt are fully deserving of being included in the list of fellows, but whose names I have omitted, simply because I have no personal knowledge of the parties, and the books of my department do not afford sufficient records to enable me to speak confidently as to their characters.

I have also omitted the whole of the assistant-surgeons, leaving it to the Council to determine whether these gentlemen should not be included as fellows as well as the surgeons, many of these assistant-surgeons being gentlemen of high professional qualifications and attainments.

I beg likewise to draw the attention of the Council to clause 8, which gives precedence to the first list of 300, to the great prejudice of the surgeons of the navy, who having been omitted in this list, can now be included in the second list only; and also to request that this error may be represented to the Secretary of State, so that by a supplemental charter, or in some other way, the precedence may be allowed in both lists, and each fellow's name stand according to the date of his diploma as a member: this act of justice being due to the officers of the public service.

I would further draw the attention of the Council to clause 5, directing that no person shall be admitted a fellow until after he shall have become 25 years of age; and, at the same time, to enclose a copy of the regulations for candidates for naval medical appointments, by which it will be seen that these gentlemen are superannuated at the age of 24, while these regulations having been formed on experience, could not be altered with advantage to the public, and yet as most of these gentlemen, either immediately on their admission into the service, or very shortly after, are sent to foreign stations, where they remain some years, this new regulation of the charter, made without any reference to them, effectually precludes the probability of those officers of the navy becoming fellows for

many years after the time appointed; and from the precedence granted to fellows according to the date of their taking the fellowship, consequently prevents officers of the navy from the probability of their having a seat in the Council, or of attaining any of the offices of the College of either honour or emolument.

I have, therefore, to request the Council will be pleased to recommend to the Secretary of State, that this claim granting precedence according to the date of fellowship, should be altered, and that the fellows should hereafter rank as in the first list, according to the date of their diploma as members of the College; or that all precedence should be abolished, the fellows being arranged alphabetically, and made eligible for seats in the Council at any period after 15 years, or such number of years standing as may be deemed advisable; without one of which, or some other similar alteration, great injustice must be done to the medical officers of the navy.

I beg to state distinctly that I have no desire that naval medical officers should evade any examination which others undergo, and I am of opinion that as these gentlemen are twice examined, and approved by the College, once as assistant-surgeon, and again before they become surgeons, they ought, if such examinations be really worth any thing, to be admitted fellows after ten years of service and of practical experience, on their certified merits, without further trouble, unless the Council mean to repudiate the diploma they now grant, in which case it may become a question as to whether it shall remain a qualification which the medical officers of the navy ought to be ordered to obtain or otherwise.

I take this opportunity of observing, that it is my invariable practice to give the assistant-surgeons of the navy the means of renewing their studies, and preparing themselves for their second examination, by granting them leave of absence for that purpose; and that, therefore, if they do not present themselves to the Court of Examiners in such state of preparation as to enable them to pass a good and creditable examination, such deficiency has been occasioned by their own neglect, and not by any want of indulgence from the public service. I therefore sincerely hope that the Court will, on every occasion, reject these gentlemen, unless they prove themselves fully qualified.

I have, &c.

(Signed) W. BURNETT,
Inspector-General of Naval Hospitals
and Fleets.

(Here follows a list of the names.)

[There is next a long letter from Sir Wm. Burnett on the education and qualifications required of gentlemen embracing the medical

service of the Royal Navy, which we shall probably make use of on another occasion.

After which follows a letter from John G. Andrews, Esq. late President of the Royal College of Surgeons, explanatory of the principles which had guided the Council of the College in selecting members for the fellowship; and a second letter from the present President, Sir B. C. Brodie, Bart. being a statement relating to the charter lately granted by her Majesty to the Royal College of Surgeons of England, and an iteration of the principles on which they had acted. Both of these have already appeared in the pages of the GAZETTE, and therefore need not be reprinted here.—ED.]

MIDWIFERY STATISTICS,

FORCEPS CASES.

To the Editor of the Medical Gazette.

SIR,

I HAVE read with much interest and attention the statistical summary of obstetric cases which occurred in the eastern district of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham, from 1832 to 1843 inclusive, as lately published in your valuable journal, and beg to remark, that it appears from the following abstract, of 26,776 women, only 34 were delivered by the forceps, *being less than one in every 787 cases!* Can this be correct?

I am, sir,

Your obedient servant,

JOSHUA WADDINGTON, M.R.C.S.
Consulting Surgeon to the Royal
Sea-Bathing Infirmary.

Marine Terrace, Margate,
August 2, 1844.

FORMATION OF FIBRINE.

To the Editor of the Medical Gazette.

SIR,

IN a late number of the MEDICAL GAZETTE, in reviewing my paper on Fibrine, published in the "Proceedings of the Philosophical

Society of Glasgow," you ascribed to me the statement that the globules of pus are of less size than those of blood. No such general statement is contained in my paper, as you will see by referring to it. My statement relates solely to the globules of pus originating in the way I described. The words "*thus originating*" have obviously been introduced to guard against the misconception into which you have fallen.

Now, without speaking of other kinds of pus, I shall merely say, that if you will take the trouble to examine for yourself the beautiful globules of the blister liquid while yet separate, and during their aggregation into a coagulum, and trace the steps by which, under other circumstances, they are converted into pus globules, I feel persuaded that you will find reason to agree with me, both as to this and to several other points on which you have expressed a difference of opinion.—I am, sir,

Your obedient servant,

A. BUCHANAN.

13, Moore Place, Glasgow.

Aug. 15, 1844.

[We are sorry for the error into which we unwittingly fell, and have pleasure in correcting it through Dr. B.'s own note.—ED. GAZ.]

THE LONDON MEDICAL GAZETTE,

BEING A
WEEKLY JOURNAL

OF
Medicine and the Collateral Sciences.

FRIDAY, AUGUST 30, 1844.

REPORTS,
BY H. FEARNSIDE, M.D.,
OF
CASES TREATED IN UNIVERSITY
COLLEGE HOSPITAL.
(For the London Medical Gazette.)

Extensive hypertrophy and dilatation of both ventricles of the heart, but of the left in particular; regurgitant (and obstructive?) disease of the mitral valves; great pulmonary congestion; bronchitis; disease of the liver; albuminous state of the urine; death, preceded by anasarca or ascites.

MARY ABERCROMBIE, æt. 18, admitted to University College Hospital, under Dr. Williams, May 27th, 1843. A girl of short stature, and ordinary conformation; a domestic servant. She was born and has always resided in London, and generally in open and healthy parts of the town; she has never suffered from privation of any description. Her mother died of phthisis; her father is still living. Neither of her parents have suffered from rheumatism, nor any affection of the heart; but she has a brother (æt. 12), who has some cardiac disease, but he never had rheumatism.

Her health has always been rather delicate. When about 7 years of age she had a severe attack of rheumatism, which confined her to bed for several weeks. She is not aware of the existence of any causes producing the disease. About a year afterwards she had an attack of chorea; but, with the exception of an inflammation of the mouth, attended with the formation of abscesses, and considerable hæmorrhage on one occasion, her health was tolerably good until about two years ago; during this time she had no palpitation of the heart, nor any other symptom referrible to that organ.

About the period mentioned she had a second attack of rheumatism, which she attributes to violent exercise, and getting wet. She was for a considerable time a patient at the Middlesex Hospital; she suffered much from palpitation of the heart, to relieve which leeches were applied over the cardiac region. She recovered slowly from this attack; and before her health was re-established, the disease returned again in a severe form, and attended with much palpitation of the heart, and severe pain in the left side of the chest. For the relief of these symptoms she was admitted into University College Hospital on Nov. 3d, 1841, under Dr. Williams: at that time a loud blowing murmur was heard with the first sound of the heart, and most loudly below the left breast, being indistinct at the top of the sternum. She left the hospital, being considerably relieved, after the lapse of about a month. After this time she began to suffer from dyspnoea more frequently and severely than she had previously done, and the palpitation of the heart was induced by slighter causes; but these symptoms were kept in abeyance for several months, during which her employment (lace manufacturing) was of a sedentary character; her general health also improved, and she gained in flesh and strength. This amelioration in her condition induced her again to return to service; but in a short time the old symptoms returned, and occasioned much suffering. She had also pain in some of the joints for a considerable time before an acute attack of rheumatism was developed. She gradually became worse; other joints were implicated, so that in the beginning of last August she was compelled to seek relief in St. Bartholomew's Hospital, where she remained about three weeks. From this time she remained in an enfeebled condition, liable to frequent and violent fits of palpitation and dyspnoea on any exertion; so that she was unable to take another situation. In December she had a fifth attack of rheu-

matism, which appears to have come on gradually, like the preceding one, and without any obvious exciting cause. She was at this time an inmate of the Middlesex Hospital for about three weeks. After her discharge she remained debilitated; began to suffer from cough, especially at night, or early in the morning; had a constant sense of oppression about the chest; frequent palpitation of the heart, and much dyspnoea, especially at night. These symptoms continued and increased until March, when she was again admitted into the Middlesex Hospital. The measures there adopted afforded her considerable relief, but since her discharge the dyspnoea and palpitation of the heart have again become very distressing; she has also suffered from giddiness, throbbing of the vessels of the neck, disturbed sleep, and loss of appetite.

Present state.—She complains of a constant feeling of weariness and languor; the surface is warm, and the hands moist; there is some but not any great amount of emaciation; there is no oedema of any part of the body. She complains of some headache, and of giddiness upon sitting up; she sleeps tolerably, but has disturbed and frightful dreams sometimes; she has frequently the sensation of scintillations, or muscæ volitantes, before the eyes, as well as tinnitus aurium. The temporal and large arteries of the neck occasionally throb violently. During a "fluttering" of the heart, as she terms it, the head is particularly affected with giddiness. The face is flushed; the lips rather livid; the eyes bright and clear; and the countenance animated.

She has no pain about the chest; respirations 28 per minute; the attacks of dyspnoea generally supervene during the night; she has a slight cough, but expectorates little.

There is no difference in the movements or vocal fremitus upon the two sides of the chest. The upper and anterior part of the chest is not very resonant on percussion upon either side; and in the same situation the inspiratory murmur is prolonged and rough, and that accompanying expiration more distinct than usual. Posteriorly, both sides appear to be somewhat dull on percussion, and the left more so than the right. A muco-crepitant rhonchus is heard over both scapular regions, and also over the right infra-scapular region. Over the middle and lower part of the left side the inspiratory murmur is rather harsh.

She frequently experiences a sense of fluttering, as well as palpitation of the heart. She occasionally has a sense of numbness in the little and ring fingers of the left hand, and this sensation sometimes extends up to the elbow. The impulse of the heart is much stronger, and more extensive than

natural, almost the whole front of the chest appearing at times to be elevated by it; it is very perceptible over a considerable part of the left side of the chest; also in the epigastrium, and for some extent to the right of the sternum. The cardiac dulness on percussion commences on the third intercostal space, and reaches to the margin of the ribs inferiorly; it extends also over a considerable extent of the left lateral surface of the chest, over the inferior two-thirds of the sternum, and for a couple of inches to the right of that bone. A loud murmur accompanies the first sound of the heart, and is most distinctly heard over the apex of the organ, less clearly over the base, and inaudible over the blood-vessels. The second sound of the heart is very distinct and clear opposite the base; but in carrying the stethoscope towards the apex, it becomes less distinct, and opposite that point it sometimes seems to be accompanied by a prolongation of the first murmur, and even succeeded by a faint morbid sound. There occurs not unfrequently a reduplication of the second sound.

The pulse at the wrist is exceedingly irregular, often imperceptible; and in frequency it averages 40 to 50 per minute. The heart's contractions are also irregular; sometimes there is an intermission, then several pulsations occur in rapid succession. The number of the heart's contractions is about 96 per minute.

The tongue is covered with a thin pale fur; no thirst, and but little appetite. She is frequently sick, especially towards the evening; the bowels are rather irregular in their action. The liver extends for about three inches below the margin of the ribs, and rises to about the usual height into the thorax. The spleen is not enlarged. The urine is acid, specific gravity 1020, and not albuminous. She is at present menstruating, the catamenia having returned about four days ago; previous to this time they had been absent for nine months; they appeared first about twelve months ago.

Treatment, and subsequent progress of the case.—Local depletion was practised over the cardiac region by means of leeches, and a combination of blue-pill, hemlock, digitalis, and camphor, directed to be taken three times daily; and the patient was placed upon middle diet. During the first fortnight after her admission her state varied much, but there was a decided improvement upon the whole; the action of the heart became less violent and tumultuous; the number of the pulsations at the wrist gradually came to correspond with those of the heart; and the dyspnoea, though often very distressing, was yet less constant in its recurrence, and its attacks less severe. After the combination of remedies mentioned had been

taken for a short time, it was omitted, and an alkaline draught, containing Sp. Æth. Nit. et Sulph. aa. ʒss., was prescribed. On June 10th the patient appeared to have taken cold; she had a frequent cough, with expectoration of tenacious semi-transparent mucus. She complained much of a sense of oppression about the chest; the dyspnoea became augmented; the respirations 36 per minute; pulse 108, and there was some heat of skin. The muco-crepitant rhonchus, which had previously ceased to be audible, now returned, and was heard over the greater part of the right side of the chest. This catarrhal attack, however, subsided in a few days, under the use of small (quarter of a grain) doses of tartarised antimony. The urine underwent some interesting changes at this time; before the attack its specific gravity was about 1020, and it contained no albumen. As the febrile accession declined, its specific gravity gradually rose to 1035; it contained an excess of saline matter, both phosphates, sulphates, and lithates, but especially of the last, which were copiously deposited as the fluid cooled. There was also a large excess of urea, and a small quantity of albumen then for the first time made its appearance, and was never subsequently found absent when the urine was examined, but, on the contrary, its proportion gradually increased. From this time there were great variations in the state of the patient; sometimes she remained free from palpitation of the heart, or dyspnoea to any extent, for a considerable time, and even passed many days in comparative comfort: at these times her appetite was good, and the improvement in all the functions very obvious. But such intervals were sooner or later succeeded by a return of the violent and irregular action of the heart; these paroxysms continued for one or several hours, were attended with great dyspnoea, headache, giddiness, and other indications of irregular circulation of blood through the brain; they were usually succeeded by great faintness and prostration of strength, and not unfrequently by sickness and irregular action of the bowels.

The physical signs relating both to the heart and lungs remained nearly as on the patient's admission, except that after an attack of the palpitation of the heart, the increased pulmonary congestion occasioned by it was rendered obvious by an extension of the space over which the liquid rhonchi were audible. Various measures were adopted for the patient's relief, and most of them were attended with temporary success: local depletion, the application of blisters over the region of the heart, sedatives, narcotics, tonics, diuretics, and purgatives, were by turns employed alone or in combination. She left the hospital somewhat re-

lieved in the early part of August, and at that time ceased to be under the writer's observation. The following additional particulars are taken, with Dr. Williams's permission, from the hospital case-book.

She was readmitted Sept. 6th, suffering from violent palpitation of the heart, and a sense of great oppression about the chest; extreme difficulty of breathing, amounting to orthopnoea; anasarca of the lower extremities, and an enlargement of the abdomen from the presence of fluid in the peritoneal sac. The pulse was exceedingly weak and irregular. Leeches were applied over the cardiac region; a combination of blue-pill, squill, digitalis, and hemlock, was given thrice a day; and a diuretic drink, containing bitartrate of potash and gin, allowed to be taken *ad libitum*. These measures, however, were quite ineffectual; the dropsy increased; she gradually became worse, and died on September 24th.

Examination of the body 30 hours after death.—*Exterior*: All the extremities, and the lower ones in particular, were immensely swollen; there was a great number of small dark spots (purpura) scattered over the face and chest. The conjunctivæ were deeply tinged yellow, from infiltration of serum.

Chest.—A small quantity of serum was found in the pleural sacs. The lungs were engorged with blood, and of rather less than the usual volume. A mass of hard calcareous matter, of the size of a chestnut, was found at the root of the right lung.

The heart presented a very large extent of surface uncovered by the lungs, and extended for two inches or more beyond the right border of the sternum; the organ was of enormous size, and much distended with blood. There was a little yellow serum in the pericardium; the membrane was transparent. The walls of the left ventricle were thickened, and its cavity much dilated. The endocardium was transparent. The aortic valves were somewhat thickened, and one of them was diminished in depth. The posterior laminae of the mitral valve was peculiarly contracted; it was thickened, indurated, and formed a semicircular, immoveable ridge, projecting in opposition to the current of blood; the chordæ tendinæ of this lamina were also thickened, and agglutinated together.

The walls of the right ventricle were thick, and its cavity large; the valves were healthy.

Abdomen.—The peritoneal sac contained a large quantity of serum.

The liver, on a section, presented a mottled appearance, from the existence of a white granular deposit in its substance.

The kidneys had the normal size and appearance.

[To be continued.]

A CASE OF FEVER

IN WHICH ANIMALCULA WERE FOUND IN
LARGE NUMBERS IN THE CONTENTS OF
THE STOMACH, AND IN THE BLOOD.

By S. J. GOODFELLOW, M.D.

Resident Physician, London Fever Hospital.

(For the Medical Gazette.)

As my only object in this communication is to point out the unusual circumstance of animalcula being present in the circulating fluid, and in the contents of the stomach, in the human subject, I shall confine myself, in stating the case, to a very cursory outline of the symptoms, and only allude to the treatment so far as to show that the animalcula were altogether unaffected by the internal remedies administered. As I had but little to do with the treatment I have an additional reason for not alluding to it more at length than for the purpose just mentioned.

CASE.—Edward Clark, æt. 17, a labourer, of tolerable stoutness of body, was seized with the usual symptoms of typhus on the 8th of last month. When I first saw him (on the 10th), he complained of some pain and sense of tightness across his chest; his breathing, however, was easy, and of natural frequency; no morbid sounds could be detected on auscultation or percussion, nor had he any cough. His skin was hot, free from any eruption; tongue coated with a greyish fur, moist; considerable thirst; no nausea, but entire absence of any appetite; bowels had been moved once or twice daily without medicine; abdomen free from tenderness or distension; pulse about 96, of tolerable power. On the following day the pain had left the chest, and no untoward symptom was observed until the evening of the 12th (4th day of the disease), when he was seized with pain in the right hypochondrium, which was soon relieved by the remedies prescribed, and he again appeared to be progressing favourably; but on the 16th he became heavy and restless, and in the evening of this day was seized with vomiting of a thin blackish fluid: his powers at this time were much depressed, and the pulse about 100, small and jerking. The vomiting and prostration continued until his death, which took place on the 22d.

On the 18th a considerable swelling was perceived around the parotid of each side, which continued, during his life, slowly to increase, to remain very hard, and to manifest no tendency to suppurate.

On the 20th, an eruption, resembling somewhat in appearance that of variola, was observed on the entire surface of the body, especially on the arms and upper part of the trunk; but it was not variolous, for it wanted the indurated character, and many other peculiarities of that eruption in its papular stage; and in this opinion I am confirmed by my friend Mr. Marson, the Resident Surgeon of the Small Pox Hospital. It was probably a peculiar form of erythema—a modification, perhaps, of the papular erythema. It never underwent any change from a few hours after it first made its appearance up to the period of his death, except becoming a shade or two darker in colour.

The internal remedies were castor oil, common saline mixture, calomel and opium, disulphate of quinine, wine and brandy.

On examination 48 hours *p. m.*, no lesion of structure in any organ, sufficient to account for death, could be detected. There was no disease whatever in the glands of the ileum. As usual, the vessels in all the mucous surfaces were much congested, as was the whole nervous system; the blood was fluid, and of a very dark colour. Some black patches in the lining membrane of the stomach, caused, no doubt, by the strongly acid contents of this organ upon the blood contained in the vessels.

On examining the fluid ejected from the stomach during life, and on the day following that on which the vomiting commenced, by the aid of the microscope, myriads of animalcula were observed in very active motion. As well as one could measure these minute organisms their length appeared to vary from $\frac{1}{1000}$ th to the $\frac{1}{2000}$ th of an inch, and their diameter (which I am convinced was the same throughout their length) from about $\frac{1}{1000}$ th to about $\frac{1}{2000}$ th of an inch. Nothing was observed by which I could distinguish the one extremity from the other, the head from the tail, although sometimes one extremity appeared certainly

larger than the other; but close and constant observation enabled me to discover that this appearance was owing to one extremity being a little out of focus, for when the whole of one animalcule was in focus no difference could be detected. Their movements, when active, closely resembled those of the small naiades so frequently seen in river-water after rain, but when they became sluggish from the inclosure of the animalcula between slips of glass for several hours, they resembled those of the larvæ of the common meat fly, *musca vomitoria*. The fluid ejected after every attack of vomiting was found to contain the animalcula in as large numbers as when it was first examined; they were also found in the sanguineous exudation from the lining membrane of mouth and nostrils. The vomited matters also contained a considerable quantity of altered blood corpuscles, epithelial cells, and a small quantity of mucus, but no trace of bilious admixture. Similar animalcula were observed in blood taken from the capillaries of the skin, but in such small numbers that they escaped my notice for several examinations. Repeated observation, however, ultimately convinced me of their existence in the blood taken from the capillaries during life. At the autopsy, 48 hours P.M., they are still seen in large numbers in the fluid contents of the stomach, and in the blood taken from both sides of the heart, and the aorta, carotid, venæ cavæ, pulmonary artery and veins, brachial artery and veins, and the femoral artery and vein. They were also found, during life, in the fæces, but they were never seen to exercise any movement in the excrement. None could be detected in the gall-bladder or biliary ducts, in the pancreatic fluid, in the urine, or in the frothy mucus in the large bronchial tubes. They were also seen by Dr. G. O. Rees, in the stomachal fluid which I submitted to his examination during the life of the patient; and by Mr. Lealand, both in the matters taken from the stomach, and in the blood after death, and both entertained no doubt of their existence, or of their animal nature. With respect to the manner in which they got into the blood-vessels I will not hazard an opinion; but this I am inclined to think, that they got into the stomach, with the blood corpuscles, and were

not introduced into the stomach with the food or medicine, and from this organ into the circulation. It will be seen from their admeasurement that their size permitted their traversing freely the smallest capillaries, and from whatever surface any sanguineous exudation was thrown out there also could these minute animalcula easily be discharged. This was the case in the sanguineous exudation from the mouth and nostrils. Most probably *similar animalcula*, at all events bodies of an animal nature, have been observed in the blood of reptiles, fishes, and even one mammal—the dog*. Although MM. Gruby and Delafond describe the entozoon which they discovered in the dog as having a larger and a smaller extremity, I am inclined to think that this apparent difference between the two extremities might be owing to the cause above alluded to. In a subsequent communication to the Academy these gentlemen state that they have examined 250 dogs, and have found the filariæ in the blood in five; no apparent difference in the health of those in whom they were found being perceptible.

August 15th, 1844.

ON THE TRANSFORMATION OF PUS CELLS INTO A MUCOUS OR FIBROUS TISSUE;

AND ON THE COAGULATION OF THE BLOOD.

By WILLIAM ADDISON, F.L.S.

[Continued from p. 692.]

Exp. 8.—Half a tumbler glassful of pus was kept for five days; at the end of this period it was perfectly fresh; there was no smell arising from it, nor was there any visible or perceptible change. A thin stratum of clear, amber-coloured, and saline liquid floated above the cells, which had subsided to the bottom of the glass. When the pus was first withdrawn, it formed with liquor potassæ and acetic acid the fibrous and mucous tissues before mentioned; but I found that it gradually lost this property, and at the end of five days, although liquor potassæ rendered the pus transparent, yet it had none of the plastic properties it displayed at first.

* London Physiological Journal, No. 1. Van Voorst, Paternoster Row.

This result shewed that the pus cells had undergone some alterations, not detectable except by the reaction of the alkali; they were incapable, at the expiration of five or six days, of forming the mucous or fibrous tissues which they did at first: hence the necessity of using freshly secreted or *newly excreted* pus for the purposes of the foregoing experiments.

Exp. 9.—A large indurated gland in the breast of a young woman, who had shortly before been suckling, suppurated. At the end of several days the abscess was opened, and a quantity of pus discharged. This pus had not the dead white, or cream-like, aspect of the former; it was more muco-purulent; it had a more plastic quality, and could be drawn out into short strings. On examining it by the microscope, there were many amorphous granular masses, myriads of isolated molecules, fibrinous filaments, and oil globules found in it. After standing a few hours the pus became gruel-like, and many more cells were found ruptured and disintegrated; those that were entire were seen to

have from three or four to five or six very minute oil globules in their interior. On adding liquor potassæ to this pus, although it somewhat increased its plastic qualities, it did not produce the elastic fibrous tissue to the extent before described; and I concluded that the pus and pus cells in this case were a nearer approach to the secreting cells of the tissue, and therefore some stages further removed from the character of colourless blood cells than in the former case, where the pus was daily thrown out in large quantities.

The following are the conclusions to be drawn from the preceding experiments. *Pus consists of a fluid element, and colourless cells. The cells may be ruptured or unruptured* (the appearance and qualities of the pus will vary according to the proportion of ruptured to unruptured cells). *The ruptured cells discharge molecules and a plastic element; the constituents of the plastic element are fibrin and albumen.* Hence the following synopsis of the composition and changes in pus.

Pus	{	Limpid saline fluid Colourless cells .	{	Unruptured	{	Molecules Plastic element	{	Fibrin Albumen.
				Ruptured				

If the fibrinous and albuminous constituents remain united after the rupture of the cells, they form a transparent mucous or fibrous tissue, which may have few or many unruptured cells incorporated in it. If the fibrin visibly fibrillates, so as to constitute a network, it forms *floculi*, flakes, clots, and false membranes, which entangle molecules and unruptured cells; while the albuminous fluid constituent, being added to the original fluid, remains as a serum or sero-purulent fluid.

On the Coagulation of the Blood.

Blood, immediately on its discharge from the human body, drops like water;

it cannot be drawn out into strings, nor does it evince those plastic qualities which it afterwards gradually exhibits, and which go on increasing up to the coagulating point*. Blood, therefore, circulating in the living vessels, consists of a limpid fluid and the cells. The cells are of two kinds, the red, and the colourless. The colourless cells are highly organized living forms, raised probably to an uniform point of vitality, containing in their interior molecules and a plastic element, the latter having two constituents, fibrin and albumen: wherefore the following exhibits the composition of the circulating blood:—

Blood	{	Blood fluid Red cells Colourless cells	{	Molecules	{	Fibrin Albumen.
				Plastic element		

* "Liquid when blood is drawn, coagulable lymph gradually becomes, first *viscid*, and afterwards solid. In the viscid state, as I have frequently observed, when it is still transparent, it has the tenacity of mucus, and admits of being drawn out in fibres and bands. This viscosity which coagulable lymph acquires in passing from a liquid to a solid form has not, that I am aware, been noticed by authors."—*Researches Anatom. and Physiol.* vol. 2, p. 239.—ED. GAZ.]

Fibrin and albumen are the two constituents, or the two forms of the plastic element; the plastic element and the molecules are the constituents of the colourless cells.

But the great change of temperature, the sudden exposure to air, and rude shocks, to which blood is subjected on its withdrawal from the living vessels, ruptures many of the colourless cells, and the plastic element and molecules from their interior mingling with the blood fluid, produce the *liquor sanguinis*. When the colourless cells are relatively numerous, the liquor sanguinis floats as a colourless stratum at the surface of the blood.

In a short time after the formation of the liquor sanguinis, the fibrin fibrillates or coagulates, forming a net-work or tissue, which entangles in its meshes the molecules and unruptured cells, forming the *clot*; while the albumen or albuminous fluid, added to the original fluid, constitutes the *serum*.

Hence, there are two distinct events upon which the coagulation of the blood depends: the first is the rupture of the colourless cells, and the formation of the liquor sanguinis; the second is the fibrillation of the fibrin producing the clot and serum (*vide* Synopsis, &c.) Any circumstance interfering with, or preventing either of these events, will interfere with or prevent the coagulation of the blood.

Now the withdrawal of colourless cells from the current of the blood, the incorporation of their contents with the tissues, and the fibrillation of fibrin, are essential stages in the process of nutrition. The coagulation of the blood is an actual transformation from blood to tissue; the events or changes, and their results, are so many stages of nutrition going on before our eyes, and the experiments I have related (p. 244, second series of Experimental Researches), is "a glaring instance" or "a demonstration" of the progress of these stages.

[Synopsis, &c.

SYNOPSIS OF THE COAGULATION OF THE BLOOD.

Blood circulating in the living vessels.	First event.	Blood withdrawn from the vessels and prior to the second event.	Second event.	Final Result.
Blood fluid Colourless cells Red cells	Rupturing { Molecules Plastic element } Fibrin Albumen	Blood fluid Molecules Fibrin Albumen (unruptured) Red cells Colourless cells	{ Fibrin, fibrillating + molecules, red and un- ruptured colourless cells } { Albumen, in solution + blood fluid }	{ Clot. Serum. }

Explanation.—The circulating blood consists of the blood fluid, the red and colourless cells. When blood is withdrawn from the body the first event is the rupture of some of the colourless cells. The molecules and plastic element, consisting of a fibrinous and an albuminous constituent, mingle with the blood fluid, producing the liquor sanguinis. The second event, which very shortly succeeds, is the fibrillation of the fibrin, which entangles the molecules, the red and unruptured colourless cells forming the clot, leaving the albumen in solution in the blood fluid, forming the serum.

menclature of the parts.
was the first who asserted that the brain is to be regarded as a development of the spinal chord, indeed it were a spinal chord diverging from the top, like the unfolding of a fan. It is to be regretted that at the time when Gall was occupied with these inquiries, viz., between the 70th and 90th years of the last century, the doctrine of the development, structure, and meaning of the organization, was much in arrears. Happily, the progress which science has made in these respects during the last four decades, and especially in the two last, has been very great.

The application of the microscope did not merely reveal a new world to us, in the same manner as the telescope has brought to view the heavens, but it has caused a new world of new organizations to spring up within ourselves, especially as regards the subject in question, and neither Albinus, Haller, nor even Gall, could have had any idea of it.

From the same cause Gall was deficient in material in investigating the structure of the brain and skull; he attempted to found a system of phrenology, but he unfortunately did not content himself with merely collecting facts, but constantly compared them with one another, in order to determine what sort of structure is connected with each in the head of this or that individual.

ON
A NEW CRANIOSCOPY,

UPON A SCIENTIFIC FOUNDATION :

*A Lecture delivered at Leipzig, on the 3d of
February, 1844,*

By DR. C. G. CARUS,
Medical Privy Councillor, and Physician in
Ordinary to His Majesty the King of
Saxony, &c. &c.

TRANSLATED FROM THE GERMAN,
By J. C. H. FREUND, M.D.

[Continued from p. 684.]

(For the London Medical Gazette.)

LET us take the well-developed brain of one of the mammalia, not to say that of man, and we shall find that the connexion of the several masses of the vesicular primitive substance is too intimate to allow an injury of the anterior brain to be exclusively attended by impairment of intellect, injury of the posterior brain exclusively by impairment of volition, and injury of the middle brain exclusively by impaired sensibility.

There can be no doubt that a dominance of the psychical tendencies within each of these organic divisions can and will be easily traced, partly by observing the consequences which arise after injuries occurring accidentally, or inflicted on purpose, and partly by close examination of the symptoms of local diseases; but an exclusive, and, as it were, fixed seat of these psychical dispositions in certain and distinct parts of the brain, can never be proved. An injury to the anterior brain (the hemispheres) is, therefore, frequently attended with impaired sensibility, and a certain degree of paralysis in the sphere of reaction; but the principal and main disturbance will certainly become apparent in common sensation and the faculty of intellect: in the same manner will an injury, or some disease of the cerebellum, principally disturb the power of motion, and produce convulsions or paralysis, but it will be also attended with aberrations of the intellect, and some derangement in common sensation. The foregoing remarks will likewise afford sufficient means to explain the reason why, in collecting carefully the great number of experiments which have been instituted by German, French, and English physiologists, this multifarious blood-

shedding has not, and cannot have been attended with universally elucidating and harmonizing results.

As soon as by superior synthesis the unity of cerebral life is perfectly established, it becomes, as will be easily understood, quite impossible to draw up one stop or register without touching the others.

Instead, then, of the wonderfully abstruse views of Gall, which I can hardly convince myself that he believed in sober earnest, viz. that the higher the organization develops itself, so much the more distinctly do the psychical radiations become fixed in certain lobules of the brain, we find that the higher the organization ascends, the greater is the freedom which the psyche gains over all the original and local relations (affinities), and the more perfectly is the inward unity of the real central mass of the nervous system established.

The question now arises, whether the system of symbols (the symbolical character), attributed to the structure of the brain, is utterly worthless? We answer this question by putting another, namely, whether it be perfectly indifferent that a man be born with a cerebral mass large and well developed, or with one that is small, and of very inferior organization? Whether it be the same that a man be born with a large cerebellum, and a proportionally small anterior brain, or, *vice versa*, with very large hemispheres and a small cerebellum? We ask, finally, if it be the same whether the middle portion of the brain be relatively more developed or not, as compared with the two other portions?

Whoever should say that it was, would fall into an absurdity, and what he said would be as groundless as if he were to inform us that it is unimportant to the faculty of sight whether a man be born with small eyes, and poorly developed, with convex or flat eyes, with eyes that, like those of an Albino, are without the pigmentum nigrum; it would be just the same as if a man were to assert that it is of no importance whatever to the energy of motion in man whether he be born with strong or with delicate muscles, with powerful or with feeble limbs.

No; it is not indifferent; and when we speak of faculties and talents which we have brought with us from our very birth, we are right in asserting it, be-

cause the organ of the psyche, viz. the brain, is very different in different individuals. How far this difference extends in both, we are able to learn in the clearest way—certainly by no anxious search after personalities—but by studying before all the differences between whole races or tribes of human beings. Let us, in the first place, for instance, consider the difference between man and woman, and we shall find that if the weight of a man's brain is 3 lb. 8 oz. per average, that of a woman is only 3 lb. 4 oz.; and the reason of its being so is the size of the hemispheres being, in proportion to the two other parts of the brain, much greater in man than in woman; the size of the cerebellum also of man being, on an average, absolutely of greater weight than that of woman. If we then compare with this which we know to be the leading features of man's character, when opposed to that of woman, we find, without any possible contradiction, a greater share of intellect and vigour (*Thatkraft*) in man, whilst both these capacities are much inferior in women; but the sphere of feelings (*das Gemüthsleben*) is, from this reason, more predominant with them. Quite a similar parallel can be drawn by the consideration of the structure of the brain and psychical life in the Negro, as compared with that of an European; of an infant as compared with an adult, in mammalia and man; and even from this it will be seen very clearly—all single cases of special personalities among men being put aside—that the primitive proportions in the organization of the brain not merely may, and can be, considered as essentially expressive of the primitive faculties of psychical life, but that they really *must* be considered as such.

A circumstance of the greatest importance for the higher development of the psyche must not here be forgotten, namely, that the intimate fibrous connection which develops itself gradually in the interior structure of the brain, re-establishes a greater freedom, and a greater independence of the psyche, by reason of its suspending partly, and by degrees, those local relations which have existed there originally.

We easily can conceive that certain unfavourable proportions may be, and really are, in part removed by the

change above mentioned; thus it is within the reach of possibility, that though the hemispheres have been originally rather inferior in development, while the middle and posterior portion of the brain has been originally of higher development, a degree of psychical perfection may be obtained, which is usually only met with in cases where the original formation of the hemispheres had been more favourable. And all this can be explained from the different cerebral masses being afterwards brought to an unity by a completely synthetical connection. Again, in instances of this kind we see very distinctly that true physiology and phrenology, far from infringing on and contradicting the doctrine of the liberty of man, affords the most decided proof in its favour.

I hope the preceding observations will suffice to give a somewhat adequate impression of what we call the *dependence* (*Bedingtseyn*) of psychical being on the physical; the physical, which surely in its primary organization is but the expression, the image, of that very idea which first was to live in this form and organization, without consciousness of itself; and then, obtaining subsequently some amount of that consciousness, was destined to develop itself into what we know by the name of the spirit (*Geist*.)

I will only add here, that consciousness which develops itself out of an unconscious life—in one word, the psyche—never remains without some influence upon the organization; and certain it is, that the better development of the conducting fibrous substance, which establishes all proportions and relations, is just as dependent on the greater exercise of the psyche, as a higher development of the muscular fibre is on the stronger exercise of the muscular frame; and in the same manner, as we very often find that a muscular system, originally feeble, attains by continued exercise a higher degree of vigour and perfection than another which, stronger and larger in its original organization, but deprived of exercise, remains consequently of inferior development, just so can a cerebral mass, though of inconsiderable volume (the spirit of consciousness in which augments, by continued exercise, the development of the inward fibrous communications of the central masses),

arrive at a higher degree of psychical energy than a brain which, originally of greater size, remained from want of employment less perfectly developed in its inward structure.

All this, besides many other precautions, deserves our consideration when we select the cerebral frame of an individual for the purpose of ascertaining by outward signs the degree of his psychical attainments.

From the same source we are enabled to explain away some apparent contradictions from time to time furnished by comparative anatomy, which have cast some doubt on the psychical meaning of the cerebral organization. It has, for instance, been said, that the cerebral substance cannot be of such importance to the psyche, because we see that many a small bird has in proportion to its whole body a much greater quantity of brain than man himself possesses; but it has been overlooked that the brain of birds is very deficient as regards its inward structure, and contains very little of that fibrous substance which is such a characteristic sign in the brain of mammalia and man, &c. &c.

This may be deemed sufficient as regards the proportions of the nervous substance and the brain, and we now come to the consideration of the skeleton of the nervous system, and especially of the skull, and it shall be our task to ascertain how far the skull is capable of affording any outward signs or symbols, in other words, of being the image of the brain, as the latter presents itself externally in the living body, and how far we from this source may feel justified in forming conclusions of peculiarities in psychical life from the configuration of the skull.

In order that we may follow out our observations with some degree of success, it is first necessary to have an idea of what is called, in the nomenclature of the osseous system, the vertebral structure, or the vertebral frame.

Oken once said: "The whole skeleton is but a repetition of vertebræ." And truly, by a strict scientific consideration of all the remarkable forms of the skeleton, to the study of which I at one time devoted ten successive years, and the results of which I laid down in my greater work on the primary parts of the osseous and scaly frame, I found this truth of Oken perfectly confirmed. In giving the world this fact, Oken was

rather instigated by an obscure feeling of truth, than by conclusions scientifically drawn.

It will suit us here to take hold only of those observations on the vertebral structure which closely refer to the subject in question, and we find that the central masses of the nervous system, especially where they attain higher development, call into immediate existence a certain tendency of organising life, by the aid of which they are surrounded with an osseous capsule, a sort of osseous ring, usually called "vertebra." And it is in this way that in higher orders of animals a vertebral column takes its origin.

Each division of the central substance of the nervous system, defined by giving origin to a large pair of nerves, becomes enclosed within a separate vertebra, and this being several times repeated gives rise to a column more or less moveable, the greater portion of which is known by the name of spine. We have mentioned above, that Gall was the first who distinctly saw and knew that the brain was but a part of the spinal chord in a higher state of development, or, as it were, the blossom of the same. One would suppose, that as a natural consequence he would have followed up that truth, and arrived at a second, namely, that the bones which are usually called the skull are nothing but vertebræ (like those of the spine) only more developed. But the progress which men make in the field of science is effected only by degrees, and so many years were required to elapse before the other truth here alluded to was discovered. Oken was the first who in the year 1807 pronounced the great fact, so important in its consequences, that the skull is a repetition of vertebræ, and indeed a vertebral column consisting essentially of three vertebral pieces. I think I was the first who proved in the year 1814, in a large work on the Brain and Nervous System, that the relation of these three vertebræ to the three portions of the brain is as certain and well defined as that which exists between the vertebræ of the spine and the separate divisions of the spinal chord. After this *apperçu* had been afforded, all well-informed men saw that it could not be otherwise, because each portion of the brain being characterised by one great pair of the nerves of sense, must,

like the different portions of the spinal cord, be enclosed within a vertebra. In all such things we are reminded of the egg of Columbus; after the fact had been stated, every one persuades himself that he knew it long before.

At the present time it must be considered as a well-known fact that the skull does principally consist of three great vertebræ, which are called the anterior (forehead), the middle (mesocranium), and the posterior cranial vertebra (occiput).

The vertebral column of the skull, however, does not end here, but continues itself into the nasal bones, where we are able to trace the presence of one greater vertebra and the rudiments of two smaller ones; but they do not contain any cerebral substance, and are, in this respect, like the last vertebra of the spine, which also does not inclose any spinal chord. For our present purpose we shall only occupy ourselves with the inquiry into the three great vertebræ of the skull, and I will only add, that there are also traces of vertebræ which bear relation to the nerves of the senses and the great sensuous organs, and have an intermediate position between the nasal vertebra and the front, between the latter and the mesocranium, and another between this and the occiput. Of these the last named is the most developed of all, and sometimes goes by the name of the auricular vertebra, from its receiving the organ of hearing and the acoustic nerve; and its presence is also indicated by numerous small bones towards the upper part, called ossa Wormiana.

If we now collect all that has been said of the brain in our preceding remarks, namely that we with certainty are able to prove the great difference which originally exists between the three cerebral substances as regards their different meaning, but that in consequence of the inward unity, subsequently established by a more intimate connection of all the three substances of the brain, those local relations of psychical life are gradually diminished; but that, nevertheless, a higher or inferior degree of development of the three substances not merely allows, but even proves in a most decided manner, our supposition for there being a disposition of a greater or less development of the three

physical faculties, then we are able to judge of what use all that will be in applying it practically for the purpose of ascertaining the meaning of the structure of the skull.

If there exists any relation between the anterior cranial vertebra—it embraces principally the front and the anterior portion of the brain, the so-called hemispheres; if the middle cranial vertebra—essentially constituted by the two parietal bones—is dependent on the middle portion of the brain; and if, finally, there exists any relation between the posterior cranial vertebra—formed by the occiput—and the posterior portion of the brain, the cerebellum, then there can be no doubt that the original (primary) psychical meaning of the three portions of the brain must be recognizable in the three vertebræ of the skull, namely perception (the intellect), recognizable in the front; the obscure sensation, or the sphere of feelings (the sentiment), in the middle part of the skull; the will (volition), and every power of reaction, in the occiput. We must not, however, forget that it is the original meaning only which will thus shew itself; and that these relations of the organization allow us to judge only of the first psychical dispositions of personality, such as they were recognizable at the period of early and unconscious formation (of the idea of the same organism).

A particular circumstance which generally contributes much to increase the importance of the cranial vertebræ must here not be overlooked. The three cranial vertebræ present, even in the perfect adult, as regards their development, a relative proportion one with another. This corresponds in a most perfect manner, not only with the brain in its full development, but also with those proportions which existed between the three cerebral substances at their earliest period, when, in short, the individual was first brought to existence. (See woodcut, next page.)

We have said, when speaking of the fœtus, that in fish the three cerebral portions are of nearly equal size, and situate one behind the other, the middle portion, however, taking the highest position, while in the grown man the anterior portion of the brain becomes so predominant that it entirely covers the two others; in the same manner also the three vertebræ of the skull

are placed in simple juxtaposition, the middle being the highest and of the greatest size in the embryo, while the reverse takes place in an adult. In him the middle portion of the brain is insignificantly small, and quite covered by the anterior.

From this it will be seen that even in the adult there is recognizable a certain relation between the cranial vertebrae, which bears a strong similitude to the state of parts which we have observed at the earliest period of the brain's existence—at a period when it was still deficient in fibrous tissue, and consequently when no internal union or blending had taken place. If, then, it be a fact that it is only at an early period of life that the different psychical directions of the three different substances of the brain, viz. perception, the sphere of feelings and volition, shew themselves as exclusive faculties, and unconnected with one another, then we become aware of how great importance it must be to observe the proportion which adheres to the three vertebrae of the skull during the whole remaining life, and from it to judge of the peculiar and original relation which existed in the same individual between these cerebral substances as regards their primary disposition, and finally to know how the different faculties of perception, sensibility, and will, were distributed in the same.

With these words we have pronounced the very first and important principles on which is founded a scientific, that is to say, a physiological, cranioscopy, or doctrine of the skull. The foundation of this doctrine is now a known fact, and whoever has faithfully followed us in the line of reasoning which has led us to it, will find himself induced

to acknowledge that the question cannot be about some vague hypothesis, but that we have to deal with the unerring consequences of simple physiological facts.

And now I think we are able to understand how the knowledge of the psychical meaning of the cerebral structure can be for the most part thoroughly applied to the skull, where it will be sure of finding all possible confirmation; we shall find, for instance, why the difference in the power of the brain connected with difference of sex is so powerfully well expressed by outward shape of the skull. The skull of women generally is smaller, and of rounder shape; the middle vertebra becomes very prominent, while the anterior (frontal) and occipital vertebra are inferior in size. Quite correspondent with that structure is the female brain itself; women possess stronger and quicker feelings, but an inferior degree of perception and energy to correspond. In man the reverse takes place.

In a similar manner we see the skull of an infant distinguished by its prominent middle vertebra, which is quite in accordance with the prevalent unconsciousness of life at that period, and of the sensation which is only the conscious reflex of the same.

It is thus that we generally recognise a great and harmoniously developed brain by the greater size and the harmonizing form of the skull, and *vice versa*. And for the same reason, it is a matter of importance, in judging of the psychical dispositions of an individual, to have a clear idea of the relation which exists between the three elementary parts of the form of the head, viz. the three cranial vertebrae. After the explanation given of the

general knowledge on the meaning of the structure of the skull, we are enabled now, in order to treat the subject more simply, to go at once to the following question:—What indications of the psychical peculiarities of different individuals do we obtain by comparing differences in the structure of their heads, and especially differences in the relative proportions of the three cranial vertebræ? Before we, however, enter any further into this subject, one circumstance particularly deserves our attention, namely, the mode of comparing this osseous frame in different individuals. Many other things should also be noticed which in this brief sketch we must pass over in silence, as, for instance, the peculiar convexity (arching), thickness, formation, and coaptation of the different parts of the skull, &c.

The first and most important thing will always be the measure, and particularly as it stands in relation to the remaining dimensions of the whole body: it is not here sufficient to know only the height, width, and length of each vertebra, but the cubical contents of each must be included in that measure, whenever and wherever such a proceeding is practicable; as we do, for instance, in examining a dried skull.

The difficulty exists in discovering such a mode of measuring the skull as on the one side may be neither too superficial nor too tedious, and therefore of but rare practicability, and, on the other hand, one which will be fit to show clearly and faithfully the essential differences in the formation of the vertebræ, and which finally can be made use of in the living body as well as in the dead.

The mode adopted by me is as follows:—

1. Measure is taken of the width of all the three cranial vertebræ, therefore (a) of the width of the front, towards the coronal suture of both sides.

(b). Of the width of the middle part of the head (middle cranium) in the direction of the eminences of both parietal bones; and

(c). Of the width of the occiput from both the lower ends of the lambdoidal suture, and behind the mastoid processes of the temporal bones.

These measures, as well as the following, will best be obtained by the aid

of callipers,* both ends of which are armed with little balls, and by calculating the respective distance of the measure thus obtained on a Parisian inch-rod.

2. In order that we may obtain afterwards the exact height of each cranial vertebra, it is necessary to take hold of an external *point d'appui* which bears a constant reference to all parts of the skull. Such a point is most satisfactorily given in the external osseous ring of the auditory canal (meatus auditorius externus). By adjusting one of the blunt extremities of the callipers either directly to that spot in the skull, or in the living subject, so deep in the cartilaginous part of the auditory canal that it comes in contact with the commencement of the osseous tube, and (a) by directing it towards the most prominent convexity of the front, the height of the frontal vertebra is ascertained; (b) by directing it towards the most prominent convexity of the parietal bones in the sagittal suture, the height of the middle cranial vertebra is obtained; and (c) by directing it towards the most prominent convexity of the occiput, the height of the posterior cranial (occipital) vertebra is obtained. And thus we shall be able to learn, if not the exact height of each vertebra, at all events their relative heights.

We have afterwards to ascertain (3) the length of each cranial vertebra, and we obtain

(a). The length of the frontal vertebra by measuring the front from the root of the nose to the beginning of the sagittal suture; (b) that of the middle vertebra of the skull by measuring the entire length of the sagittal suture, or the upper edge of the parietal bones; and (c) the length of the occipital vertebra is obtained by measuring the length of the occiput, beginning from the highest middle point in the lambdoidal suture to the posterior edge of the foramen magnum. (The last mentioned measure can be taken with exactness in the dried skull only).

In this way we easily obtain, in six or nine numbers expressing the essential form and size of each skull, a dis-

* Callipers (according to some etymologists, from the French, "*caliber*") measure the distance of any round, cylindric, conical body.

tinct and well-circumscribed picture of a tabular form; and, at the same time, we may, by way of notes, mark down all the extraordinary formations which we meet with in one province of the skull or other (as, for instance, any overlapping of the parts, or non-symmetrical formations of the vertebrae of the skull, &c. &c.), adding, also, the proportion which the configuration of the head bears to the form of the whole body.

In taking the measure in a living subject, two lines must be deducted from the amount of each measure for the thickness of the skin.

[To be concluded in our next]

ON A NEW METHOD OF MAKING MEDICATED TINCTURES.

To the Editor of the Medical Gazette.

SIR,

HAVING lately been engaged in examining the strength and properties of the official tinctures, I am induced by the results of my experiments to notice several objections to the common method of making tinctures by maceration, as directed in the London Pharmacopœia, and to suggest a modification in it which seems to offer advantages not only over the old method, but likewise over the more recent French method of percolation, as recommended in the Edinburgh Pharmacopœia.

Against the common process of maceration one of the chief objections consists in the difficulty of shaking or stirring effectually the large quantity of materials which are usually employed at one operation in pharmaceutical laboratories; another is the length of time which the process occupies; and a third imperfection is, the waste of spirit by evaporation during the act of stirring, and the final transfer of the moist materials from the macerating vessel to the filter, through which the turbid tincture must be eventually passed.

In order to obviate the imperfections alluded to, and to exhaust the solid, or deprive it of its soluble components, with less labour and in a shorter period than is practicable by the method commonly pursued, I suggest that the two parts of the process, namely, maceration and filtration, which are now performed separately, should be con-

ducted simultaneously, and the solids packed beforehand in the bag which is afterwards to serve as a filter. The process is recommended by its simplicity, and may be readily accomplished by suspending the bag of solids just under the surface of the solvent, so that all parts of the bag be immersed, and a space left between its lowermost end and the bottom of the macerating vessel.

In this process no shaking or stirring is requisite; it may be said to be automatic; and as soon as the spirit begins to act on the solid, a coloured tincture will be seen to gravitate through the colourless and lighter spirit by which it is surrounded. In proportion to the rapidity with which the heavier tincture gravitates, a corresponding bulk of lighter spirit ascends, and is carried or forced into contact with the solid suspended at its surface. Thus, in a short time, a descending and ascending current will be established throughout the fluid, and will continue to move as long as the solid contains any soluble extract, or the solvent has become saturated, and incapable of dissolving an additional quantity.

One of the best illustrations of this process is afforded by the phenomena which may be observed during the making of Tinctura Kino, with the proportion of ingredients directed in the London Pharmacopœia; a brief description of which will serve as an explanation of this new application of a principle long familiar to scientific chemists.

Take, for example, 126 grains of kino, in small fragments or coarse powder, and inclose them loosely in a calico bag, large enough to contain as much again, and secure the mouth of it with a fine string. Next choose a glass bottle, stoppered, with a wide mouth capable of holding four fluid ounces of spirit, and pour into it three fluidounces of Spiritus rectificatus, having a specific gravity of 0.838 at 60°. Then suspend the bag of kino by its string, attached to the neck of the bottle, just below the surface of the spirit, and close the bottle, as represented in the annexed sketch No. 1.

The bottle should be left at rest, and almost as soon as the kino is immersed its dissolution commences; in proof of which a bright red stream of tincture

begins to descend, and for a short time remains at the bottom of the bottle, distinct from the colourless spirit above and around it; but in the course of a few hours the red stratum will have increased in thickness, and eventually ascended to the upper surface.

The tincture of kino thus produced will be perfectly clear, and its physical properties at the end of three or four days will correspond precisely with a tincture made with kino of the same quality, and spirit of equal density, mixed in the same proportions, and macerated together in a bottle for the space of fourteen days, according to the old method.

Equal quantities of the same kind of myrrh, treated respectively with rectified spirit of equal density, by the two processes, yielded two tinctures which also possessed analogous qualities; and the tincture made by the new method was perfected in three days. The tinctures of jalap and opium were likewise perfected in about the same period, and that of catechu in two days. Those of yellow and pale cinchona, and that of compound gentian, have also been prepared with great facility by the same method.

But as the solubility, in the same kind of menstruum, of the animal and vegetable compounds used in making the officinal tinctures, varies with their nature as well as with the temperature of the neighbouring air, heat promoting, and cold on the other hand retarding it, and as no advantage is invariably gained by shortening the process of maceration a few days, but, on the contrary, some risk might be incurred of failing to exhaust the solid, it will be safer to protract the maceration by suspension of large quantities to seven days, although a less time might serve in many cases.

The subdivision of the solid will also influence the rate of its dissolution; and in general fine powders are more quickly acted on by menstrua than

coarse powders; but for some reasons the latter are preferable, and the directions given in the London Pharmacopœia as to the disintegration of the solids used in making tinctures are sufficiently explicit.

The absorbing power of dry porous solids, and the reciprocal affinities between them and spirit, are able to overcome considerable impediments to the free circulation of the latter through the bag and its contents; but unless attention is paid to the texture of the bag, and the mode of packing it, time will be lost, and the perfect success of the method endangered.

Fine flannel or calico will answer the purpose of a filtering bag very well; and in this the dry solids should be loosely packed, so as to allow space enough for their expansion on being immersed in the spirit, and for the circulation of the latter through them.

But some solids, as cinchona, used in making tinctures, are more bulky than others, as kino, and the proportions of spirit are definitely fixed by the directions given in the London Pharmacopœia; and it will be found in consequence, that when a very bulky substance is to be macerated by suspension, that the quantity of spirit will not be sufficient to cover the bag and solid in a vessel of the cylindrical form. In such cases it will be necessary to choose a vessel of the requisite capacity, and of a conical shape, inverted and truncated, as delineated in the annexed drawings, No. 2 and 3.

No. 2.

No. 3.

It may be constructed of either porcelain, earthenware, or glass, furnished with a lid to fit closely, and with a tap at its bottom through which the spirit may be drawn off.

In this shaped vessel, from the capacity of a champagne glass to that of a jar containing many gallons, the macerating bag of proportionate dimensions may be suspended at the requisite

height by regulating the length of the strings, either fastened to the outer rim of the vessel, or to projections made on purpose within it; and so arranged as to keep the bag just clear of the sides, and as high as possible above the bottom of the vessel, but at the same time under the surface of the spirit.

The quantity of tincture which can be decanted or drawn off after the maceration has been completed is always rather less than the original quantity; and when porous solids are used, the loss of spirit may be obviated in part by submitting the bag to pressure; but a portion will be permanently retained by the solids, and the expressed tincture will be turbid. When, therefore, the loss of a small proportion of spirit is not an object with the pharmacist, the solid may be more effectually exhausted, and a clear tincture obtained, by submitting the bag and its contents to a second maceration in a fresh portion of spirit, equal in bulk to that which is retained by the solid after the first maceration.

But if no pressure is thought to be requisite, less spirit would be wasted by absorption, and time saved, by modifying the arrangement, and substituting a fine sieve-shaped receptacle for the bag, suspended at the proper height, as before described, or by internal projections, and in which the solids may be loosely strewed, as in the annexed outline sketch, No. 4.

I have found this arrangement answer very well with catechu and myrrha; and it has the advantage of exposing a more extensive surface to the action of the solvent, and retaining a less quantity of spirit by absorption, than when the bag is employed.

The foregoing remarks relative to making tinctures apply also to the medicated wines of the London Pharmacopœia; and I have prepared by this process the Vinum Ipecacuanhæ in less than forty hours, and the Vinum Col-

chici in three or four days, of equal strength respectively to those made by the old process in fourteen days. The same plan may be followed in making infusions; but the macerating bag should be open as the coffee-baggin, and the boiling water poured on the solids to be infused, in a vessel somewhat resembling the sketch No. 4. having a spout through which the infusion may be poured when cold.

Mr. Warrington, of Apothecaries' Hall, has kindly lent his valuable assistance in trying the proposed method on a large scale; and I am also indebted to Mr. Whitfield, the Apothecary of St. Thomas's Hospital, for several useful practical suggestions; the testimony of both of these gentlemen tends to strengthen my own opinion of its general applicability to the purposes of pharmacy, and of its novelty.

I remain, sir,
Your obedient servant,
HENRY BURTON,
Physician of St. Thomas's Hospital.
Jermyn Street, Aug. 1844.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

—
On Calculous Concretions in the Horse, Ox, Sheep, and Dog. By W. J. T. MORTON, Lecturer on Medical Chemistry and Veterinary Materia Medica. With Plates. London: Longman and Co.

CALCULOUS concretions are found in the alimentary canal, in the urinary organs, and occasionally in the salivary glands and ducts, lungs, liver, and other parts. Those taken from the stomach were formerly termed bezoar stones, and were esteemed of great virtue as prophylactic talismans. Stomachic calculi in the lower animals are principally composed of the phosphates of ammonia and magnesia, which are always found in the outer horny husk of the seeds of the grasses, and particularly in large quantity in the bran of flour. They are caused by a derangement in the process of digestion which prevents the assimilation of the food, and allows the phosphates to aggregate around any foreign body in the stomach. Liebig informs us that the large crystalline concretions

which are met with in the cæcum of millers' horses, consist of the phosphate of magnesia in combination with ammonia.

Mr. Morton divides intestinal calculi into three kinds—the triple phosphate calculi, consisting principally of the ammonio-magnesian phosphate, with the phosphate of lime and animal matter—the oat hair calculi, consisting chiefly of the hair of the oat with similar phosphates—and the mixed calculi, usually termed dung balls. The greater number of intestinal calculi consist of the triple phosphate. Mr. Morton observes that these calculi vary considerably both in size and number. They are from the bulk of a small pea to that of a man's head. Sometimes only one or two will be found, and this is commonly the case with the larger ones. Occasionally, such impact themselves in the sacculi of the intestines, and remain there altogether harmless, giving no signs whatever of their existence. At other times they become dislodged, and cause much irritation and colicky pains, followed by inflammation and death. Now and then they have been voided with the excrement. Their structure is singularly uniform, and, I may even add, beautiful. Some adventitious substance exists in the centre of each, around which the phosphates have arranged themselves in equidistant circles, or in lines radiating from a common centre, there only to be interfered with by the mechanical action that may have been induced by the vermicular motion of the intestines. Some difference in colour of the layers will be seen, the darker alternating with the lighter. I am rather inclined to think that this depends upon a modification of the attractive force. Their density is by no means uniform. Some on their external surface are pale-coloured and friable, breaking off in scales; others are dark coloured, hard, smooth, and polished, as if recently taken from the hands of a lapidary. M. Girardin analysed one of the specific gravity 1.741, and found it to consist of

Ammonio-phosphate of	48.
magnesia	
Phosphate of lime . . .	19.
Water of interposition . .	14.
Animal matter	0.80

	100

Mr. Morton is of opinion that the earthy and other matters taken into the stomach and intestines never form true calculi when the digestive powers are healthy. Dr. MacLagan analysed an oat hair calculus which was as large as two closed fists, and weighed rather more than eight ounces. The surface was lobulated, and covered in many places with patches of light brown crystals. These, as well as the greater proportion of the earthy matters, consisted of the phosphates of ammonia and magnesia. The bulk of the mass was made up of the hairs and husks of oats. The composition of the whole was as follows:—

Organic matters and moisture	52
Soluble salts	8
Phosphate of lime	6
Ammonio-magnesian phosphate	28
Silica	6

100

By the aid of the microscope the oat hairs may be seen in these calculi. Dung balls, or mixed calculi, are made up of coarse, indigestible, excrementitious matter, mixed with portions of the calculi already described, and many foreign substances, such as pieces of coal, gravel, &c., the whole being agglutinated together by the mucus of the intestines; and they are most commonly met with in horses that are voracious feeders. Mr. Bowles, of Abergavenny, states that he often finds a large quantity of coal and stones in the intestines of horses that work under ground. Mr. Simonds is of opinion that calculous concretions are by no means so frequently met with in sheep as in oxen. In rams it is by no means uncommon for the vermicular extremity of the penis to be closed by an accumulation of earthy matter, which has the appearance of crystallized carbonate of lime.

Phlebolites, or vein stones, often attain

3 A

the size of a common pea; more frequently they are smaller, and sometimes they do not exceed a millet seed in size. Otto* saw one in the Anatomical School at Strasburgh, of the size of a hazel nut. They are usually of a yellow colour, and consist of concentric lamellæ, and are more frequently of an oval than a round shape. According to the analysis of John and Gmelin, they are principally composed of carbonate and phosphate of lime with animal matter. Different opinions have been entertained respecting their formation. Mr. Hodgson thought it not improbable that phlebolites were formed in the surrounding parts, and found their way into the veins by progressive absorption. Meckel entertained an opinion that they were formed like encysted tumors. Andral states that calculous concretions sometimes push the internal membrane before them, and descend with them into the cavity of the veins. The membrane, he adds, becomes thin, and forms a true peduncle to the concretion. The observations of Dr. Carswell prove that there is first formed a small coagulum of blood in the veins, and that in the centre of this clot a little nucleus of concrete layers gradually appears. After a time the red part of the blood is absorbed, and fibrine makes its appearance with the usual physical characters. Then a certain arrangement can be perceived taking place in the fibrine, forming lamellæ, the central one first formed apparently becoming cretaceous; and this cretaceous induration takes place throughout the different lamellæ until the whole is converted into a solid phlebolite. In the point towards the distal extremity of the vein there is sometimes a little nucleus of blood or fibrin, which becomes a concretion, and thus the phlebolites get a caudal extremity.

Mr. Morton analysed a portion of one of the phlebolites, and found that its investing tunic was made up almost wholly of albumino-fibrin. "A portion of its interior," he states, "being boiled for some time in distilled water, did not undergo any perceptible change whatever, nor did it impart any sensible properties to the water. In a solution of caustic potassa it became dark-

coloured, but emitted no ammonia. Another portion, about five grains, being placed on a piece of platinum foil, and subjected to the influence of heat by the aid of a blow-pipe, blackened, and threw off copious exhalations having the odour of burning animal matter. It then became white, and on being weighed was found to have lost nearly one-half its weight. The residuum quickly dissolved in dilute hydrochloric acid with effervescence, and the gas evolved rendered lime water turbid. The solution being filtered, and rendered nearly neutral, the oxalate of ammonia threw down from it an abundant precipitate, and on adding an excess of water of ammonia to it, gelatinization took place. The microcosmic salt threw down no precipitate, and the hydrosulphate of ammonia caused no discolouration, proving the absence of the metallic oxides. The inference deducible from the above analysis is, that the concretion consisted of animal matter—nearly one-half, the remainder being the phosphate and the carbonate of lime."

Gmelin analysed some phlebolites taken from the human subject, and found them to consist of

Animal matter	27.5
Phosphate of lime . . .	53.5
Carbonate of lime . . .	15.5
Magnesia and loss . . .	3.5

100

A concretion, reported to have been taken from the thoracic duct of a horse, was composed of the phosphates, and was invested with a membranous covering. Mr. Barth removed some calculi from the spongy portion of the clitoris of an ass, which were composed of the urate of soda and phosphate of lime.

This work is creditable to the author, and the plates are well executed, especially those which are illustrative of the oat-hair calculus.

On the Decrease of Disease effected by the Progress of Civilization. By C. F. H. MARX, M.D., Professor of Medicine in the University of Göttingen, &c. and R. WILLIS, M.D., Member of the Royal College of Physicians, &c. London: Longman and Co.

WE are happy to see this excellent little work, which, as our readers know,

* Transactions of the Veterinary Medical Association, in Cyclopædia of Practical Medicine.

appeared originally in its English dress in these pages, printed separately, and made accessible to all classes of readers. That which has seen the light under our own ægis we are naturally restrained from speaking of in terms either of praise or dispraise; this much we may be allowed to say, however, that we have only heard the work mentioned in terms of the warmest commendation, whether by professional man or lay-man, into whose hands it has fallen.

In its distinct form the work is most appropriately inscribed to Mr. Chadwick, a gentleman who may be said to have been the first in this country to see the important bearings which the labours of medical men have upon the well-being of society, and who first systematically used the information which they possess for the enforcement of truths, and the elucidation of questions of the very highest importance in political science. We are pleased to see the exertions of such a man as Mr. Chadwick appreciated by such competent judges as Drs. Marx and Willis; the compliment they pay him is as well-timed in connection with their subject, as it is well deserved. Mr. Chadwick's claims to general attention being considered. To give the work on the *Decrease of Disease* to our readers quite complete, we shall quote the dedication to Mr. Chadwick, and the preface by the English editor.

To Edwin Chadwick, Esq. Barrister at Law, &c. &c.

Dear sir, — There is no man in this great empire, whose name can be so appropriately placed at the head of an essay on the *Decrease of Disease by the Progress of Civilization*, as your own. Allow us the pleasure of placing it there, of expressing, at the same time, the high sense we entertain of your labours, and of associating you, though not of our profession, with its very highest offices, — the diminution of the causes of disease, and through this, the elevation of mankind in the intellectual and moral scale. Your *General Report on the Sanitary State of Towns*, is, beyond all question, one of the most valuable contributions that has lately been made to the noblest department of medical science, — the Art of preserving the Health of the Community, — and will

have an influence upon the human family as long as it exists.

With an expression of our sincere respect, and warmest sympathy with your labours, believe us, dear sir,

To be yours very sincerely,

C. F. H. MARX.

B. WILLIS.

June 18th, 1844.

Preface by the English Editor.

My distinguished friend, Dr. Marx, won all hearts on the occasion of his visit to England in the summer of 1841, and I have always been anxious publicly to show him in what dear remembrance I hold his short stay among us, and how much I prize his friendship and esteem. It seemed to me that I could do this in no better way than by making him known in England in our mother tongue, and I have for some time intended to give to my professional brethren one or other of his smaller works in an English dress. The excellent essay of my friend, "*On the Decrease of Disease effected by the Progress of Civilization*," enables me, I trust, to present him to a wider circle than that which is merely professional, and thus to extend the sphere of his influence and usefulness.

Physicians have no place in the body politic; it would be well for humanity if they had; for who, since the revival of letters in Europe, have been foremost in every undertaking whose object has been to extend the boundaries of knowledge, and to exalt mankind? Who know half so much of the wants and the wishes, of the joys and the sorrows, of the community? — who are the friends and comforters, in adversity especially, of persons in every grade of life — from the sovereign and the peer, to the wretched outcast of the streets, houseless, homeless, friendless else? Who disarm pestilence of its power, and give Jenners to the world? Who follow in the field through the thickest of the fire, not that they may aid destruction in her work, but, God-like, that they may staunch the wounds she makes? In one word — the medical profession, medical men. The servant of religion hath not more of true sanctity about him than the good physician; the service, indeed, that was rendered of old in special temples to the

Divinity conceived in one of his most beautiful attributes, is not yet extinct upon earth, but has its ministering priest, ennobled by Christianity, in every worthy member of the medical profession. Oh! let society cherish and exalt its medical community: let it become aware, that if *science* cannot aid it in its struggles with disease, neither can *ignorance*; that nothing can by possibility be known to the quacksalver and empiric that is not familiar to the educated physician; that a youth of preparation, and a life, however protracted, of ceaseless devotion to his art, are still too little to familiarize him with all the varieties of disease, and the means of meeting them successfully; and that there is no access to the Temple of Medicine save through an intimate knowledge of the laws by which we live, and move, and have our being.

In publishing this little work, I ought to say that I have rather paraphrased than translated my friend; that I have often added to his words, sometimes retrenched from them, sometimes made him speak otherwise than he does of himself.—I had not only to make him speak English, but also to speak as an Englishman: in short, I had done so much, that it became necessary for me to submit the proof-sheets of the work to Dr. Marx, and it is with his concurrence and wish that my name is associated with his own on the title-page.

CICERO.

THE BILL FOR THE BETTER REGULATION OF MEDICAL PRACTICE THROUGHOUT THE UNITED KINGDOM—No. III.

WE have lived long enough in the world to be well aware of the folly of attempting to convince mankind, by the soundest arguments and the most definite facts, against their will and

previous conclusions. For friends and companions we have to find men who think and feel as we do ourselves. When we begin to argue with any one on making his acquaintance, we are already half way towards a quarrel with him—the thermometer of mutual confidence and esteem, at all events, falls to zero; and, though we may nod as we pass, and even give each other "good day" afterwards, still it is all done coldly, and with indifference. So we fear will it be with this medical bill: they who have been instrumental in suggesting its provisions to the minister will look upon us coldly because we differ from them, and venture even to find fault with what they doubtless deemed faultless. All the world, professional and lay, who had no hand in concocting the bill, however, are agreed as to the impolicy of removing the few and slender barriers that formerly existed between the ignorant public and presumptuous empiricism; and we trust that Sir James Graham, as he did not contradict Mr. Macaulay, when that gentleman said, that "he understood the right honourable baronet as intending that the bill should be considered in the recess, in order that any modifications which might be agreed upon as desirable might be introduced into it next session," will yield to the general persuasion on this important point; and, further, that his advisers will not oppose themselves too resolutely to his adding a single clause, to the effect "That whosoever from this time henceforth presumes to practise medicine or surgery without having had sufficient education, and been found competent by one or other of the legally constituted boards, shall be held guilty of a misdemeanor, be liable to be proceeded against before a magistrate, and, upon conviction, be held obnoxious to fine and imprisonment." We particularly deprecate the onus of proceeding

against incompetent persons by way of action at law, being thrown upon any of the medical bodies that either exist, or that may be called into existence. It is an odious duty; it has always been looked upon with very jealous eyes by the public, and even been made a handle against the profession of medicine. Thieves and pickpockets are respectable persons in our eyes, in comparison with those who, without the knowledge necessary, tamper with the lives and well-being of their fellow creatures; so that we conceive the nearest police-office tribunal high enough to decide in the cases of unlicensed practitioners of medicine.

The second clause of the Bill enacts, "That a Council shall be established, which shall be styled 'The Council of Health and Medical Education;' and that One of Her Majesty's Principal Secretaries of State shall be a Member of the said Council, in right of his office as Secretary of State; and that the Regius Professor of Medicine in the University of Oxford, the Regius Professor of Physic in the University of Cambridge, the Regius Professor of Physic in the University of Dublin, the Regius Professor of Clinical Surgery in the University of Edinburgh, and the Regius Professor of Surgery in the University of Glasgow, shall be Members of the said Council in right of their several Professorships; and that the other Members of the said Council shall be *One* Physician and *One* Surgeon, to be chosen by the Colleges of Physicians and Surgeons respectively; *One* Physician and *One* Surgeon to be chosen by the Colleges of Physicians and Surgeons of Scotland respectively; *One* Physician and *One* Surgeon to be chosen by the Colleges of Physicians and Surgeons of Ireland respectively; and *Six* other persons whom Her Majesty, with the advice of Her Privy Council, shall deem fit to be Members of the said Council."

In the *Times* newspaper of Friday, August 23, will be found some excellent observations upon this clause. The writer there regards the Medical

Bill from the proper point of view, as a measure deeply interesting to the community; and the particular clause in question he even regards as bearing hard and prejudicially on some of our characteristics as Saxon men, one of whose grand distinctions from all other men has consisted in this: that we have been used to self-government. And certain it is that our state administration has really had very little to do with all that comes most immediately home to us as denizens in this realm of England. Our executive appoints us judges, indeed, expounders of the laws, presidents who regulate our proceedings in our civil and criminal courts, but twelve of ourselves finally try the cause and find the verdict. In our guilds and corporations we have ever a voice potential in all that concerns us as citizens; and in the broad system of religious toleration which we have established, we secure perfect freedom in matters metaphysical.

"Regarding the medical profession," says the *Times*, "as comprising a large body of educated men, exercising a very considerable influence on the people, though not always very ostensibly, and rather domestically than politically, it is impossible for us not to deem the constitution of the proposed 'Council of Health and Medical Education' a matter of national importance.

"Hitherto the principle of self-government has been carried out in the medical profession, and with indisputable benefit to themselves and the nation. Considering the vast extent of the interests confided to their care—the health and much of the physical welfare of the whole people—considering also that to their freedom of inquiry and action we owe the gradual progress of the science of medicine, the testing and rejection of what is empirical, the steady adoption of those principles which have stood the trial of repeated examinations, it is not too much to assert, that to place them now under what will be no better than a Government board, is a most rash and uncalled for experiment; and yet this is

what Sir J. Graham's measure would effect.

"The Council is to be composed of 18 members. Of these, one of the Secretaries of State—of course the Home Secretary, at present Sir J. Graham himself—is to be the President, with a double vote, and with power to nominate the Vice-President. Five Regius Professors are to be *ex officio* members; and six other members are to be nominated by the Crown. Each of the Colleges of Physicians and Surgeons of England, Scotland, and Ireland, is to choose one of the six remaining members. Of the 19 votes which the Council will have, 13 will be those of nominees of the Crown; and, leaving out of the calculation the casting vote, there will be two Government votes against every professional vote—a majority quite sufficient to secure to the Home Secretary the virtual control of the Council. But, as if this majority were not sufficient by itself, the members are to be paid 'such salaries as shall be from time to time allowed by the Lord High Treasurer or Commissioners of Her Majesty's Treasury,' who are also to have the power of allowing (and consequently of disallowing) such reasonable travelling expenses 'as they shall think fit' to the members; so that, unless the professional members should happen to be quite independent of private practice, and able and willing to incur the expense of performing their duties gratuitously—a lot we should suspect not likely to be that of the best men whom the colleges could choose—they will be subject to the *argumentum ad crumenam* enforced with all the logic of the Home Secretary. An equally impudent attempt to increase ministerial power and to carry out the principle of centralization—to reconcile the sham of a popular election with the reality of an absolute nomination—we never met with; and the despotic authority to be vested in Sir James Graham's Council is as astounding. The various colleges of physicians and surgeons are 'from time to time, when required by the said Council,' to lay before them schemes of their courses of study and examinations, 'and the said Council shall be empowered to make from time to time such changes in any of the schemes so laid before them as to the said Council shall seem expedient;' so

that the whole of our medical and surgical colleges throughout the kingdom, all their professors, lecturers, and students, and all the future members of the profession, are to be subjected to the virtually irresponsible fiat of the Council under the presiding control of the Home Secretary for the time being. As if to insure that the Council should not let well alone, but that they should *of necessity* make changes in the schemes laid before them, it is to be expressly enacted that they '*shall endeavour to procure, as far as is practicable and convenient, that the qualifications and fees for testimonials shall be uniform, according to the nature thereof, throughout the United Kingdom.*'

"No one who has the slightest acquaintance with the existing state of the profession can hesitate to denounce this as a piece of gratuitous mischief. Its direct, immediate, and inevitable tendency is to destroy at one blow much of that competition between the different schools, to which, perhaps more than to any other cause, we owe the rapid progress of the profession within the last few years. It is the tendency of all old-established institutions to become rather passive, and therefore we are not invidious when we refer to the stimulus which was given to Bartholomew's by its being undersold (one of Sir James Graham's bugbears is underselling) by the Aldersgate School, to the struggle with Bartholomew's for supremacy which Guy's has for years been making, and to the new spirit infused into all the London schools by the exertions of those attached to hospitals in various parts of the country, as being direct evidences in favour of an absence of precise uniformity in the course of study and the expense of education. Why, the very life of every profession consists in the freedom of its action and of honourable competition between its members; and here steps in Sir James Graham with a measure for medical reform directly calculated to destroy it, with the power placed virtually in his own hands to carry that measure into operation, and with the duty self-imposed of bringing all medical education in future to one unvarying level."

There is something of this with which we agree; there is also something of it from which we dissent. It

cannot have been written, we should say, by a medical man, though it have a smack of particular medical information. We do not believe, for example, that the competition between medical schools has had any the slightest influence on the progress of medicine, or that St. Bartholomew's Hospital was ever stimulated by being undersold by the Aldersgate Street School. The prices at the two places particularly quoted continued at their former unequal rates; but the school beyond the hospital may be said to have died a natural death some time ago. Some of the cheap schools have even done much to degrade the profession; the laxity of discipline there has prevented the teachers of the larger establishments from enforcing the attendance of the pupils in the way they would have done; young men have not always entered to the cheap schools that they might save money; they have sometimes done so that they might have their schedules filled up without the necessity of attendance. It is not the amount of fee that is all; it is even much less than the talent and zeal of the teachers; and we cannot help thinking that uniformity of fee would do much good. But we are anticipating what we shall have to say on this head, and our business is not to argue with our giant contemporary; it is to discuss this medical bill paragraph by paragraph, and to try the stuff of which it is made in the fiery furnace of independent criticism.

With the elements, or rather the kind of elements, of which "The Council of Health and Education" is to be composed, we find no fault; but what we fear is, that the materials are not available; that they cannot be brought together. The principal Secretary of State, and the six nominees of the Crown, could always be reckoned on; so, perhaps, might the Physician and

the Surgeon who are to be chosen by the Colleges of Physicians and Surgeons of London respectively; but who shall say as much for the Regius Professor of Medicine of Dublin, of Oxford, of Cambridge, or for the Regius Professor of Surgery of Edinburgh, or the Surgeon and the Physician to be chosen by the Colleges of Surgeons and Physicians of Scotland and Ireland respectively? Will they leave their chairs, and their practice, at the rate per chance of two or three thousand a year, for a week's or a month's sojourn in London in discharge of their duties as Councillors of Health and Education? We rather think that they would not, and that the Council would be, independently of the powerful considerations which the *Times* has pointed out, the mere tool of the single influential man, surgeon or physician, who happened to have the ear of the principal Secretary of State for the time being, and who was its president.

Whilst we admit the great advantage that would accrue from uniformity, or all but uniformity of medical education, we still think that this could be perfectly well secured by a plurality of supreme councils, one for each division of the kingdom, and holding its sessions regularly in London, Dublin, and Edinburgh. There would be no difficulty in these three councils coming to the most perfect understanding upon all essential particulars; a representative from each, meeting together in congress once or twice a year, or oftener, if requisite, would settle everything; and it seems to us that the country would thus be better served, and the independence of our natures better preserved than they could be by any system of centralization which can be devised.

We also think the conjunction of "Health and Education" somewhat unfortunate here. There should be a

Council of Health in every great town, independently of the councils of medical education (which we would have in alliance, yet distinct) in England, Scotland, and Ireland. The wants of society point to the necessity of something of the kind more and more imperatively every day; but the institution of Councils of Health need not be connected with a Bill for the regulation of the medical profession. The members of such councils would of course be in principal part medical men, indeed; but their grand business would rather be referable to police than to physic, in the vulgar sense of the word.

MOVEMENT IN THE PROFESSION.

WE never knew the members of the medical profession perfectly unanimous before: there seems absolutely but one mind in regard to that absurd proposition involved in Sir James Graham's Medical Bill, the removal of all restrictions whatsoever on the exercise of the profession of medicine. We presume that from Land's End to John o' Groat's, district meetings of medical practitioners will be held, for the purpose of petitioning, in the next session of Parliament, against so much at least of the measure as refers to this point. Marylebone, distinguished for its political organization, as well as for the number and high respectability of the medical men who inhabit the borough, has led the way, and shewn good taste as well as talent in the conduct of its meeting, held last week, for the purpose of declaring its sense of THE BILL.

Mr. Pennington, a very old and esteemed practitioner, was called to the chair, and it was resolved, "That an association be formed, to be called the Medical and Surgical Association of the Borough of Marylebone, for the purpose of watching over and protecting the interests of the profession generally, and that the business of the association should be carried on by a

President, Vice-President, and thirty members of committee, who would have power to add to their number."

After which Mr. Pennington was elected President, and Messrs. Probert, Clayton, and Squibb, were elected Vice-Presidents. Among the members of Council we observe the names of Messrs. Ancell, Baker, Bird, J. B. Browne, Bryant, Cradock, Hodding, Houlton, Maclure, Richardson, Vickers, &c. &c.

The second resolution was to the effect—"That it is the opinion of this meeting that the Bill introduced into the House of Commons by Sir James Graham, Bart., in its present shape will be highly injurious to the medical profession generally, but more especially to that branch denominated the general practitioners, which class of the profession has been yearly increasing both in respectability and knowledge, and now at the present day numbers amongst its members men as well and as carefully educated as any in the other branches of the profession; inasmuch as its operation would be to throw open the practice of medicine to men, wholly unfit, from want of previous education and study, to be entrusted with the care of the lives of her Majesty's subjects."

The third resolution was in these terms—"That it is the opinion of this meeting that the Society of Apothecaries, since the passing of their Act in 1815, have done their duty admirably, and to the great advantage of the public; and that they have elevated the standard of education of the general practitioner to its present creditable position. It therefore deprecates, most cordially, any attempt to repeal the Act of 1815, unless another tribunal be instituted that will continue the education of the general practitioner under the control of his own grade, and contain some penal enactment for the protection of the public from intrusion of unqualified practitioners."

There may be some difference of opinion as to the mode of effecting all that is desired; there is none as to the affirmation of the principle of protection, which at the Marylebone meeting was viewed as especially necessary to the general practitioner. It is only his right; but we think that he is much less interested in the matter than

the community: we insist on protection to the community.

At Bedford, a meeting of medical gentlemen was held on the 19th. It was resolved that a Committee should be formed, for the purpose of taking steps with regard to Sir J. Graham's bill.

At Leamington a very numerous and most respectable meeting was held on Thursday the 22d instant, within the walls of the Warneford Hospital, Dr. Middleton in the chair; at which the following petition was agreed to:—

To the Hon. the Commons of Great Britain and Ireland in Parliament assembled.

The Petition of the undersigned Physicians, Surgeons, and Apothecaries, of Leamington, Warwick, and the surrounding districts,

Humbly sheweth,—That your Petitioners, whilst they hail with satisfaction those portions of Sir Jas. Graham's proposed "Medical Reform Bill" which they believe will tend to exalt the character of their profession, have read with deep regret and one feeling of disappointment that clause in the Bill which, by repealing existing protective enactments, and removing all restrictions from the practice of medicine, would open the profession to any individual however uneducated or unqualified.

That your Petitioners recognise, in the legal qualification at present required in those who would practise medicine or surgery, a necessary guarantee to the public that such practitioners are competent to undertake the highly responsible and arduous duties of their profession, and a just protection to those who, by diligent study, and at a very great expense, have thus qualified themselves.

That, as in framing the proposed Bill it has been considered expedient that certain qualifications shall be required in those few members of the profession who may be appointed to any public situations, your Petitioners would humbly submit to the consideration of your Honourable House, the more urgent necessity of affording to the public in general, in the far more extensive field of private practice, the same protection, which has been, very wisely, thought necessary for the inmates of hospitals and workhouses.

That a result, which your Petitioners feel assured would be deeply deplored by your Honourable House, would inevitably follow the passing of the Bill in its present form, viz.: a retrograde movement in medical science in this country, and the ultimate destruction of the respectability of the profession.

Your Petitioners, therefore, now appeal to your Honourable House, in the confidence that their interests and the public good will be duly considered at your hands, and they respectfully, but earnestly, entreat that, if it be deemed expedient to repeal the Act of 1815, your Honourable House will see the justice of enacting some other law whereby the public may be protected, and the interests and honour of the medical profession efficiently maintained.—And your Petitioners will ever pray, &c.

The good sense and right feeling displayed in this petition appear to us altogether irresistible. The ground of dissent from the proposed bill is our own, and we think it the correct one.

THE LATE TRIAL OF BELANY FOR THE MURDER OF HIS WIFE;

THE VALUE OF THE MEDICAL EVIDENCE GIVEN—THE IMPORTANCE OF EDUCATED MEDICAL MEN TO THE COMMUNITY.

Amongst the eventful scenes annually witnessed in the Courts of the Old Bailey, we can call to mind few of a more painful character, and of deeper interest, than the trial of J. C. Belany for the murder of his wife, a young and beautiful woman, by administering to her prussic acid, which occupied two entire days in the past week.

Our readers have no doubt perused, in the ordinary channels of information, the details of this mysterious case—the admirable address of the Solicitor-General, who appeared for the prosecution—the evidence of the numerous witnesses—the extraordinary letters—the eloquent appeal of Mr. Erle in behalf of the prisoner—the summing up of the judge—and the verdict of acquittal. Upon these it does not fall within our province to comment; but, in the exercise of our duty as editor of a medical journal, we cannot pass unnoticed the evidence of the medical witnesses, and its important bearing in

supporting the heinous charge laid to the count of the prisoner.

Medical men have not always appeared to advantage in courts of justice; with the gradual improvement of education, however, they have gone on improving, and the appearance they made on the trial of Belany was to the last degree creditable to them; nothing could be more precise, nothing more free from prejudice or partizanship, than their evidence: and this is precisely what it ought to be. The excellent courses of lectures on medical jurisprudence, which are now an integral part of our medical education, have doubtless contributed in no small degree to this satisfactory result.

The chief points which the medical evidence went to establish were—

1. The generally healthy state of the body of the deceased; the absence of disease of the heart, to which the prisoner had falsely attributed his wife's death; and the real cause, poisoning by prussic acid.

2. The total neglect of any effectual means of restoring the deceased after she was discovered labouring under the effects of the poison, and the prospect of recovery had proper remedies been resorted to.

3. The probability that the poison was put in the way of, or administered to, the deceased by the prisoner.

We have already, in a previous number of this journal, borne brief testimony to the discretion of Mr. Garratt, the surgeon who was first called to the aid of Mrs. Belany, but arrived after her death, in causing a coroner's inquiry to be instituted in this mysterious case. The careful post-mortem examination of the body made by him and by Mr. Curling of the London Hospital, not only proved the absence of any important disease, and brought to light the real cause of death, but excited fears of this discovery in the wretched husband's mind, which it cannot be doubted led him to make a most important statement as to the cause of his wife's decease, and the mode in which the poison was taken.

It appeared by the evidence of the mistress of the lodging house, and of her servant, that the unfortunate lady continued to breathe for more than twenty minutes after swallowing the poison—a period which would have afforded adequate time for resorting to

remedies to counteract its deleterious effects. We hesitate not to declare our conviction from this fact, that the quantity taken could not have been by any means an overwhelming dose; and we question whether a case ever occurred to any medical man which offered a fairer chance of recovery, had proper measures been promptly resorted to.

We entirely concur with Dr. A. T. Thomson,* “that if a person lived twenty minutes after taking prussic acid, the probability would be in favour of recovery, if remedies were applied;” and with Mr. Curling, “that so long as the deceased breathed, he should not have despaired of recovering her.” Dr. Letheby stated, “I have since made experiments with the prussic acid I got from Mr. Donahoo (the druggist of whom Belany purchased the poison), upon animals, and restored them by the application of ammonia and the affusion of cold water. By those means I restored a cat in ten minutes. I had given that cat between ten and twenty drops. I also tried an experiment upon a horse, to which I administered prussic acid twelve times the strength of the two per cent. acid, and by the same means restored the horse, though it was lying upon the ground in convulsions, and in the incipient stage of death. I continued the remedies for about twenty minutes, and the horse was restored.”

Now what were the means employed for the recovery of this poor lady during this period, the twenty minutes before death? Placing the hands and feet in warm water, applying a mustard poultice to the stomach, and bathing the temples with vinegar; and the prisoner said he would bleed her, but she had no pulse. Adopting the favourable conclusion of the jury, our blood boils as we write, to think that a human being was thus cruelly left to perish—that life was allowed by the husband slowly to ebb away when the means of saving his wife were so readily at hand. Nothing could be more decisive than the evidence of the medical witnesses on this point. They all bore testimony to the efficacy of remedies the most easily obtained—such as hartshorn, cold affusion, and artificial respiration; and to the utter inutility

* Times' report.

of the inert means resorted to. As Mr. Curling well remarked, "none but energetic stimulants could be of any service in counteracting the effects of so powerful a poison." And yet the miserable wretch, the prisoner, stood by with a lancet in his hand, prepared, as it appeared, by blood-letting, to guard against the possibility of the unfortunate woman's recovery. When asked by the mistress of the house whether he would not "send for a doctor," he replied that he himself was one. The unhappy wretch is a thousand times more blameable, setting aside all idea of criminal purpose on his part for the moment, than John Garland, who eviscerated Mrs. Dent, by pulling nineteen feet of her bowels out of her belly into a heap under the bed-clothes. He was a "doctor," forsooth! He, the inhuman brute, stood coolly by, looking on at the death agony of his young wife, with his own flesh and blood, in the shape of a child, several months old, under her heart; and only suffered assistance to be brought when it could be of no avail! If Garland were prosecuted and convicted of mal-practice, and punished for his ignorance, why is not Belany proceeded against on a similar ground?

Belany is another instance of a man practising medicine without adequate education, and of the advantages that the public would be likely to derive from the profession of physic being thrown open to all and sundry who had but effrontery and dishonesty enough to set themselves up as practitioners. No one who has gone through the course of study now required of medical men, and who has solemnly been charged with the responsible duties of the practitioner, could by possibility be found to behave as this man did.

Before commenting on that part of the medical evidence which tended to show the probability that the poison was put in the way of, or administered to, the deceased by Belany, it is necessary to remind our readers that the prisoner, in the communication to Mr. Garratt, made after the discovery of the cause of his wife's death, stated "on the previous Saturday morning he was about to take some prussic acid, which he was in the habit of taking for an affection of the stomach, and was endeavouring to remove the stopper from

the bottle; and as he had some difficulty, he used some degree of violence to it with the handle of a tooth-brush, and the consequence was the breaking the neck of the bottle. Some of the acid was spilt; the remainder he put into a tumbler, and placed on the drawers at the end of the bed-room." The prisoner then said, "I went into the front room for the purpose of getting a bottle wherein to place the acid. Instead of doing so, I began to write some letters to my friends in the country. I had been there but a few minutes when I heard a scream from the bed-room. I immediately went in. My wife exclaimed, 'Oh dear! I have taken some of that hot drink; give me some water, some cold water!' She immediately became convulsed." It also appeared that the prisoner stated, that "when he entered the bed-room his wife told him what had occurred, and that he took the tumbler from which she had drunk the poison out of her hand."

We shall now extract from Dr. Letheby's evidence that part where he says—"I have made numerous experiments with prussic acid upon the lower animals. The first effect which the administration of prussic acid produces upon the lower animals is the appearance of a peculiar giddiness, of a disposition to run round, as if the head was affected; then the respiration becomes irregular; subsequently there is a scream. Perhaps before that scream is uttered the animal drops, at the same moment, after two or three violent respiratory efforts, which produce a cry, a shriek, or a scream; convulsions follow, with foaming at the mouth; and in a longer or shorter time, according to the quantity of the acid administered, death ensues. I have not had an opportunity of seeing its effect on the human subject. After the shriek or scream, all sensibility and volition ceases. In my judgment, a person after giving that shriek would not be able to walk or converse."

Dr. Thomson, who was the next witness examined, remarked:—"The effects of taking it are those which have been so clearly explained by the last witness: giddiness, faintness, convulsions resembling those of tetanus or lock-jaw, and screaming. When the symptoms have advanced to a scream, the powers of volition are gone. After

the scream it would be impossible for a party to talk, so as to describe what had happened."

The evidence which we have just adduced, founded chiefly upon experiments made on the lower animals, could not fail to make a stronger impression on the minds of professional men than on those of persons unacquainted with medicine and the action of poisons. To us, well initiated in these subjects, the prisoner's statement appears wholly unsatisfactory and improbable; but we are not surprised at the Judge, after pointedly inquiring of the medical men examined, whether they had ever witnessed a case of poisoning by prussic acid, and receiving a negative reply from each of them, observing to the jury, "The medical men had told the jury, that with the scream that was spoken of all volition and power of speech would cease; but then it must not be forgotten that the judgment of these gentlemen must be tempered with this caution, that none of them had ever witnessed the effects of prussic acid on the human body;" a hint sufficient to impair in no slight degree the weight of evidence, which we have reason to believe was not given without the most anxious and careful consideration of the subject.

In further proof of the improbability of the prisoner's statement, was adduced the striking circumstance, that the landlady and servant who entered the small room in which the deceased lay, detected no peculiar smell, although, if his account be true, some acid was poured into a tumbler, and left for a few minutes in the room. Dr. Thomson stated, "the smell of prussic acid is very peculiar. If any be spilled in a room the odour remains a considerable time, unless there is much movement in the air of the room. If it were in a tumbler the odour would be strong—if it were lifted to the top the odour would be perceived." We have tried the experiment; we have poured a small quantity of the acid (Scheele's preparation) into a tumbler, and after leaving it for five minutes in a small room, have entered the chamber, and we could scarcely believe it possible that any one possessing the ordinary sense of smell could fail to notice the remarkable odour pervading the apartment. We think, then, the absence of all odour of the acid strongly corroborative of the other points which

impugn the truth of the prisoner's statement. Had the poison been mixed with the solution of Epsom salts in the adjoining room, carried into the bedroom, and immediately swallowed by the deceased lady, scarcely any smell would have arisen.

There is one point in Dr. Letheby's evidence, which, we think, was either not rightly understood, or not quite rightly used. In his cross-examination by Mr. Erle, he states, "prussic acid is one of the easiest poisons to detect after death." Now, whilst we admit that this is the case *immediately* after death, we know that prussic acid both evaporates so quickly, and so readily suffers decomposition, that we much doubt whether it could be detected in the stomach, even at the end of a few days after death. At any rate, arsenic, the mineral acids, and many other poisons, if not more easy of detection than prussic acid, are yet more permanent, and to be detected after a much longer period. Dr. Letheby probably did not perceive the bearing of the question put to him, and therefore did not answer it in a way that was calculated to elicit the truth. His reply, at all events, was made a point of by the Judge, who in his charge certainly omitted no circumstance which could tell in favour of the prisoner; but desired the attention of the jury to it particularly, as it was unlikely that a medical man, contemplating the circumstance of murder, would have selected for his purpose "one of the poisons most easy of detection." We think that he who has knowledge of poisons would select that which he knows to be most speedy and most certain in its operation; which produces sudden death, and whose effects to ignorant by-standers would look like what they conceived to be "a stroke," or a disease of the heart, when told so, that disease being rendered the more likely by family predisposition: a momentary struggle, and six feet of cold earth to make all snug, would be the poisoner's maxim; and prussic acid, backed by the Eastern Cemetery, are the precise elements required. Baron Gurney was certainly wrong in this inference. Had he been a medical man, he would have used the very point which he made a principal means of saving the prisoner at the bar, as one of the principal and most powerful means of condemning him.

We have now adduced the chief part

of the medical evidence for the prosecution, which tended to inculpate the prisoner, and we leave it without further comment. We have no space to analyse the other important evidence and numerous facts adduced at the trial, which influenced the jury in the decision to which they arrived. Although the indictment was not sustained, we believe that this prosecution, which we feel bound to say was most fairly and impartially conducted, cannot fail to promote the ends of public justice: a person was destroyed by a subtle poison; a studied attempt was made to conceal the cause of death; that attempt was defeated, and the cause revealed by the searching inquiries of skilful medical men. In fine, we say: *Let the community see to it, that they secure themselves in the presence of well-educated practitioners of medicine.*

REPORTS OF CASES
OCCURRING AT
THE WESTMINSTER HOSPITAL:
WITH REMARKS.

By B. PHILLIPS, Esq. F.R.S.

*Very severe Fracture of both Thighs and
Legs, followed by Tetanus.*

THOMAS TERRY, *et.* 16, was admitted into Northumberland Ward on the evening of Friday, May 17. He had been assisting in shifting timber in a barge, and was struck down by the swinging of a large piece. The injuries he suffered from the accident were very severe. He was immediately brought to the Hospital, and seen by Mr. Phillips: he found the lad cheerful and uncomplaining. Upon examination, it was found that he had sustained a simple fracture of each thigh at its middle third, and a compound fracture of each leg below its middle. In the legs, the injury done to the soft parts was very great; a good deal of blood was lost; the bones were protruding and broken into many fragments. The pulse was scarcely perceptible, and the surface of the body was rather cold, but the intelligence was perfect.

A consultation was held on the case, and the decision came to was, that, although the injury done to the legs was probably too great to be repaired, yet his present condition did not warrant amputation.

He was then placed on Earle's bed, the limbs in a double-inclined position, and the legs maintained in their position by means of jacks and pillows. The state of collapse was combated by means of warm brandy and water, but for some hours there was no evi-

dence of rallying; when slight reaction became apparent, he complained of pain, and he was then ordered a draught containing \mathfrak{ss} . of brandy, and \mathfrak{mxxv} . of Battley's solution, warmth to the feet, &c.

He passed a tolerably quiet night, but there was much lassitude in the morning. It was evident that the left foot was dead—circulation had ceased in it, and it was cold and discoloured. The right foot was warm and natural. He took gruel and tea during the day, with some brandy, and the same dose of Battley at night. He slept at intervals during the night, and held his ground. The left leg being more painful on Sunday, a large poultice was laid over the bandage, and it lessened the pain. The same kind of food was taken during the day, and the draught at bed-time.

On Monday morning he reported himself as being better, and expressed a desire for food—"a soft boiled egg, and salt;" this was taken with appetite, and during the day he had another beaten up with his tea. To-day the right foot became cold, discoloured, and vesicated. The bandages were removed, and a poultice laid over that also.

Rept. Haust. *h. s. s.*

On Tuesday the report was favourable, but the tongue was loaded with a whitish fur; the bowels had not acted since the accident. A pint of warm water was administered as an enema, and a copious evacuation followed.

Cont. Food and Draught as before.

On Wednesday there was a sensible improvement. The tongue was much cleaner, the desire for food greater, and the pulse 92; the legs discharging freely. The food taken was milk, beef-tea and two eggs, with some brandy; and his draught at bed-time.

Thursday.—His countenance is improved; he is more cheerful; tongue tolerably clean; pulse 88.

Rept. Med. &c.

Friday.—Much the same. The process of separation is fairly established.

Cont. Med.

Saturday.—The bowels being still confined, an enema of warm water was again administered.

Sunday.—Passed rather a restless night, complaining of pain in the leg and thighs.

Cont. Med. and Food as before.

Monday.—Has not slept during the night; countenance anxious; bowels relaxed, and the stools very offensive.

\mathfrak{R} Tr. Opii, \mathfrak{mxxl} ; Mist. Cretæ Comp. \mathfrak{ssj} . M. \mathfrak{ss} . Stis horis sumend. and to have Brandy \mathfrak{ssj} . in addition.

Tuesday.—Slept at intervals during the night; diarrhoea still continues; complains very much of the pain in the thigh.

To have the Draught at bed-time, with Solut. Morphine Mecon. ℥xx. in addition.

Attacked during the night with slight tetanus, which gradually increased during the day.

℞ Hyd. Chloridi, Opii Gum. aa. gr. j.; Ft. Pil. 2ndis horis.

Wednesday. — Bowels relaxed; spasms still continue.

To omit the Calomel and Opium, and take Tr. Opii, ℥xx. omni hora.

Thursday. — The spasms are less violent than yesterday, but there is difficulty in swallowing. The tetanus continued during the day and night, and he died on the morning of Friday.

REMARKS. — It is very rarely that a patient survives for many days such severe injuries as were sustained by this poor lad. The condition of either leg of itself, and in the absence of any other complication, would have justified immediate amputation, but the amount of injury altogether was so great, the powers of life so shaken, and the pain comparatively so inconsiderable, that it was thought proper to give him time to rally, and there appeared reason to hope that his youth and stamina might have enabled him to bear up against the shock. However, when the irritation consequent upon the work of separation was set up, the pain increased, his nervous system became too excited, and tetanus was developed, which destroyed his life within three days of its manifestation. Calomel and opium, of each a grain, were exhibited every two hours: after eight doses the bowels became relaxed. The opium was then continued every hour alone. At no period were the spasms so violent, at no time was the mouth so closed, as to prevent his taking food; still the progress of the disease was not retarded by the absence of spasmodic action, and there was no narcotism.

In the last case of tetanus treated at this hospital, cannabis was largely used, and extract of belladonna, so as to develop its poisoning effect, but they exercised no influence in arresting the progress of the disease.

Dense Cyst over Patella extirpated.

Jane Wisbart, æt. 27, housemaid, admitted under Mr. White in June 1844, having an enlarged bursa situate over the ligamentum patellæ the size of an egg. She states that two years previously there was a similar swelling on the same knee, which was blistered, and a variety of other means used, for its dispersion, but without effect. At length, from the great inconvenience it occasioned her, she had it removed by the knife; and that between three and four months afterwards, she again had pain and swelling on the knee, which have been gradually increasing.

Upon her first presenting herself, which was several weeks before her admittance into the hospital, the knee was treated by blistering, &c. but without any decrease in the size; the cyst was then injected with a solution of iodine, but without effect. The patient wishing to be freed from it, was taken in, at her own request, to have it removed by operation. On the Saturday after her admission, Mr. Phillips made an incision immediately over the tumor, and dissected it completely out; there was no bleeding, and the wound was brought together by strapping, &c. The patient has gone on very well since, the wound has completely healed, and she is discharged cured.

REMARKS. — This case is curious. It seems that a few months ago the bursa over the patella was dissected out, it is said completely, and yet in that short period of time, although she had knelt but little in the interval, a new bursa, with very dense walls, an eighth of an inch thick, is developed. Supposing the statement to be correct as to complete extirpation on the first occasion, the case is unusual; but if only a portion of it was removed, then the singularity is much lessened, because we see similar results elsewhere. The resistance offered to the development of inflammatory action upon the injection of a strong solution of iodine, and the density of the walls, leads us to the belief that the sac was an old one. Not long since we had a somewhat similar cyst over the popliteus muscle, which resisted several blisters, and other counter-irritants, but it immediately yielded to iodine injection.

CORRESPONDENCE BETWEEN THE PRESIDENT OF THE COLLEGE OF SURGEONS & SIR W. BURNETT.

We have been requested to insert the following Letter from Mr. Andrews, President last year of the College of Surgeons, to which that of Sir William Burnett, published in our last, has particular reference.

College of Surgeons, March 14, 1844.

The Council of the Royal College of Surgeons of England have been sensible from the beginning that the task imposed upon them by the new charter of selecting a limited number of members to be placed in the list of fellows, was one of considerable difficulty, in the execution of which, however great might be their care and circumspection, it was impossible for them to avoid leaving many persons more or less dissatisfied with their proceedings. They have done what was required of them to the best of their ability; and at any rate they feel conscious that they have used their endeavours to make the selection altogether on public grounds, without favour or prejudice, and

uninfluenced by private motives; and they are glad to avail themselves of this opportunity of explaining the principles on which they have acted.

It is well known that the great majority of the members of the College of Surgeons are less engaged in the practice of surgery than in that of medicine, or pharmacy, or midwifery, and that many of them have arrived at great eminence in these other departments of the medical profession.

But the Council, keeping in view the objects for which the College was especially established, were led to believe that in the nomination of fellows it was their duty to regard chiefly the qualifications of members as practitioners in surgery, or as improvers of those sciences which tend to the advancement of surgery, and to look to such qualifications as giving the best claims for admission to the fellowship.

1. In accordance with these views they first placed in the list of fellows the surgeons of all those hospitals in England and Wales which are recognized by them as schools of surgery; and they did so, knowing that the surgeons of large hospitals, as a body, have the best opportunities of experience in surgery, and that they are the persons principally consulted in private practice in surgical cases.

2. But they found that in several parts of the kingdom there are persons having considerable reputation as surgeons, and called into consultation on surgical cases by the practitioners in the neighbourhood, although they have no connection with hospitals, and the Council thought it their duty to place the most eminent of such persons in the list of fellows also. Some of the individuals already nominated are of this description; and there are others whose names may properly be added before the expiration of the first year from the date of the charter. It is plain that in the execution of this part of their duties great circumspection is required, lest improper names should be inserted and proper ones should be omitted.

3. Not being themselves well acquainted with the qualification of military and naval surgeons, and being at the same time unwilling to overlook the claims of this meritorious class of practitioners, the Council allowed Mr. Guthrie, who at that time filled the office of president, to apply for assistance to the heads of their respective departments, Sir James M'Grigor and Sir William Burnett, and also to the chairman of the Court of Directors of the Honourable East India Company. The Council have no means of knowing the exact terms in which Mr. Guthrie made the application, but they did not doubt, at the time, that he requested to have a list of such medical officers in the public service as were the

most distinguished for their surgical attainments. Soon afterwards they received communications from each of the above-mentioned gentlemen, recommending several persons as fit to be nominated as fellows; and the Council, without further inquiry, adopted these recommendations, admitting every one of them to the fellowship.

4. There being in London several practitioners in surgery, who, though not connected with hospitals, were considered as eligible to the Council under the former charter, and according to the usages which then prevailed, the Council thought that they were called upon to admit them also to the fellowship. If they had neglected to do so, these gentlemen would have complained that they had been hardly dealt with, in being, without any fault of their own, deprived of their ancient privileges.

5. Some individuals have been admitted as fellows, not on account of their reputation as practical surgeons, but as having distinguished themselves by their investigations in the kindred sciences of natural history, anatomy, and physiology. One of these is Mr. Owen, the distinguished conservator of the museum of the College. Another is Dr. Mantell, the eminent geologist and zoologist; a third is Mr. Gulliver, an assistant-surgeon in the Household Brigade, a Fellow of the Royal Society, and the author of some important physiological papers, which have been thought not unworthy of being published in the *Philosophical Transactions*; and a fourth is Mr. Newport, a practitioner in pharmacy as well as surgery, who has received the Royal Medal from the Royal Society, and is the President of the Entomological Society.

6. A very few other names have been inserted in the list of fellows, for special reasons; being principally those of teachers of anatomy, midwifery, or some other branch of medical science, who had been recognized as such by former acts of the Council.

The Council are ready and willing to add to the list of fellows the names of any officers in the public service who are distinguished for their surgical or scientific attainments, which have been overlooked formerly, as soon as they have obtained the information which is necessary for the purpose. That they have no wish to do otherwise is sufficiently proved by the nomination of Mr. Gulliver.

After they received Sir James M'Grigor's communication, the Council found that he had omitted altogether two departments of the army; namely, the Ordnance, and the regiments of Guards. The Council, without any application having been made to them on the subject, have already nominated as fellows some of the surgeons of the Ordnance, and they will think it their

duty to inquire which among the surgeons of the regiments of Guards are the most deserving of the same honour. But the Council cannot accede to the demands made by Sir James M'Grigor and Sir William Burnett, the effect of which would be to throw the whole management of the College into the hands of the military and naval surgeons, or rather of those to whom, as the heads of their respective departments, these gentlemen are accustomed to look for patronage and promotion.

(Signed) JOHN GOLDWYER ANDREWS,
President of the Royal College of Surgeons
of England.

MIDWIFERY CASES.

NOTE FROM DR. F. H. RAMSBOTHAM.

To the Editor of the Medical Gazette.

SIR,
In the last number of the GAZETTE there is a note from Mr. Waddington, relative to the summary of cases that occurred under my superintendence in the Eastern district of the Royal Maternity Charity, which lately appeared in your valuable periodical. Mr. Waddington rightly states that in the last twelve years 26,776 women were attended, and that the number of those delivered by the forceps was only 34, "*being less than one in every 787 cases*," and he concludes by asking, "can this be correct?"

For Mr. Waddington's satisfaction, I beg to assure him that the tables from which he has taken his calculation are *perfectly correct*; and that although the generality of the women relieved in my district are not delivered under my own immediate observation, such arrangements have been made as to prevent the possibility of any unusual occurrence happening during the labour of any of them without my cognizance.

I am, sir, your obedient servant,

FRANCIS H. RAMSBOTHAM.

14, New Broad Street,

LECTURES ON THE NATURE AND TREATMENT OF DEFORMITIES,

*Delivered at the Orthopaedic Institution,
Bancroft Square.*

By R. W. TAYLOR, F.R.C.S.E.
Surgeon to the Institution.

UNTIL a recent period deformed patients were left almost entirely in the hands of mechanists, and it is, as you are aware, but a very short time since the scientific treatment of deformities was introduced into this country. It is not more than twenty-eight years since the principles on which we are now successfully treating deformities were practised by Delpech, and afterwards published, so that time has not yet elapsed for this treatment to have become general; nor can opportunities have presented themselves for a very extensive field of inquiry, save at institutions especially devoted to the treatment of deformities, and perhaps at the large hospitals of the metropolis. And here I cannot omit to mention the benevolent exertions of Mr. Charles Harris, who, having experienced relief in his own family, devoted himself to the formation and support of this Charity, for the benevolent purpose of extending the same benefits to the poor, which he knew the rich could command. It is to Mr. Harris's unceasing benevolence and unwearied exertions that we are indebted for its present existence.

By the term deformity is meant any and every deviation from the recognised symmetrical proportions of the human frame; but the word is more definitively applied to those irregularities of form which consist in a partial deviation from the natural position of the body, unaccompanied by malformation of the general original structure. I may here observe that it is probably a conviction on

the part of the profession that club feet are actual malformations, that we are to ascribe the unaccountable fact of this species of distortion having almost to the present day been left without rational or truly scientific attempts made to remedy it.

This, however, is one of those useful lessons that teach us the necessity of perpetual study, and remind us that however great the advances already made, the field of inquiry is still open and inexhaustible; that the healing art is not one in which we can ever rest supine, but, on the contrary, that it calls for constant activity and unwearied perseverance. It must be continually borne in mind that science is ever progressing, and that it is the duty of every worthy member of the profession diligently to search out, and impartially to investigate, any new system which has for its object the alleviation of human suffering, notwithstanding its departure from the trodden path of established practice. True it is, that there are, and ever will be, "Will-o'-th'-Wispes" presenting themselves under every form of quackery, and that it behoves us to use every effort to distinguish the true from the apparent, the essential from the ideal; yet must we never be deterred by timidity or prejudice from endeavouring to advance the science of which we have the honour to call ourselves professors. I say honour, because there is no higher pleasure, no greater distinction, no more exalted exercise of the human mind, than that profession which has for its object the benefit of our species, and the mitigation and removal of those ills to which all of mortal birth are subject. To the visitation of deformity this remark applies with double force, for the deformed have been regarded as loathsome in body and depraved in mind; they have often isolated themselves from their fellow creatures; persecution of them has even been sanctioned by the Mosaic ceremonial, which admitted the unblemished alone to the dignity of the priesthood. Possessing all the

feelings, and susceptible of all the impulses which animate the breast of man, frequently morbidly sensitive from the consciousness of their deformity, adorned with genius, gifted with wit, graced by fortune and by birth, crowned with learning,—still is the deformed man exposed to the derision of the heartless, and is shut out from the world simply because nature has played some freak by which he differs from his fellow mortals.

Nevertheless, history records the names of many whose spiritual excellence overcame their bodily deformity: Socrates, Æsop, Alexander the Great, whose head is said to have inclined slightly to the left shoulder, the illustrious Lord Burghleigh, Pope, Talleyrand, Sir Walter Scott, Flaxman, and Byron, were all deformed in different degrees. I believe the sole instance recorded by the classic poets of female deformity is a woman named Kutila, who lived to be a hundred; she is spoken of by Pliny, and also by Juvenal. A facetious Englishman, named Hay, has written an *Essay on Bodily Deformity*, in which he good-naturedly and sensibly vindicates those labouring under such an infliction from the stigma so ungenerously cast upon them. He was himself deformed.

It is my intention in the ensuing lectures to confine myself as much as possible to facts; for facts alone can be of service in the present condition of our knowledge of deformities. Theory is undoubtedly useful, but it too frequently by its false colouring destroys or obscures the principal objects that ought to be kept in view, and withdraws our attention from that which is really useful, to that which exists only in the imagination, and which not unfrequently impedes the progress of the subject with which it is connected.

It must be evident that to advance the theories that must occur to the minds of those who have had numerous opportunities of practice in one or other of the branches of surgery, would be to clog and encumber it to the apprehension of those who have not possessed similar advantages; and they will derive much more useful information from facts themselves. For in what does the knowledge of surgery consist? If analysed, we discover that it is an accumulation of facts handed down from one generation to another.

The principles laid down by Delpech, in his *Orthomorphie*, published at Paris in 1828, are comprised in the following rules:—

1st. "A tendon to be divided must not be exposed; and its division should be made by turning the instrument on one side, so that the line of the incision may not be parallel to the division of the skin; without this precaution risk of exfoliation of the tendon is incurred."

2nd. "Immediately after division of the

tendon, the divided ends should be brought into contact with each other, and kept in this position by a suitable apparatus during the entire period necessary for their union."

3rd. "Inasmuch as it can only take place by the intervention of an intermediate fibrous substance, this substance, before it has become firm, can, and should be, extended gradually and carefully, until it has assumed a degree of length equal to the shortened muscle."

4th. "When this degree of extension has been effected, the parts should always be fixed in the position, and kept so until the new substance has acquired its requisite degree of consolidation."

These, gentlemen, are the principles upon which we are now acting, and from which we depart but in the slightest degree; they embody the entire doctrine of the treatment of deformity, and have only to be followed out carefully to insure success. There can be no question that had Delpech been spared to enjoy the common number of years allotted to man, he would have extended to every variety of deformity the new views which he so graphically announced. It was not only in deformity in the feet, and the physiology of the division of tendons, that Delpech shone so conspicuously, but also on lateral curvature of the spine and on dislocations of all kinds, on which subjects his works must be considered as second to none in originality and in correctness of principle. It is gratifying to find, that Stromeyer, who has been fortunate enough to extend the treatment of the distinguished surgeon of Montpellier, has generously acknowledged the merits of Delpech; for he says, "Although the division of tendons has been recommended long since as a mode of removing certain contractions, yet the credit of having set this operation on a proper scientific basis undoubtedly belongs to Delpech, inasmuch as he showed the peculiar advantages derived from a new fibrous substance between the divided ends of the tendon, thus giving to this method of operating its true practical value, and enabling us to avoid rendering inactive the muscles whose tendons have been divided;" an acknowledgment on the part of Stromeyer which does equal credit to his head and heart. In his work "*On Operative Orthopædic Surgery*," Stromeyer observes—"Delpech laid it down as a rule, that the surgeon should encourage the formation of sufficient substance between the two divided ends of the tendon to maintain the function of the muscle, and should not destroy the new union by immediate extension, but commence extension some days after the operation: this rule is most important for the safe performance of orthopædic operations, and its value should be duly estimated. The

idea that the elongation of the muscle is effected through the cicatrix is a false one. The extent of the substance or cicatrix is quite inadequate for this purpose. In some cases of peroneus the gastrocnemii are two or three inches too short; and, in wry neck, the sterno-mastoid is equally short, yet the cicatrix, after the cure, is but a few lines long. The elongation of the muscle must be effected in these cases at the cost of its contractility, and thus the incision of its tendon acts not only on its mechanical, but also on its vital properties, and, by the temporary diminution of its irritability, its contractile power is diminished, and any increase of it prevented. This view is confirmed by observations made in cases where the tendons of sound muscles have been lacerated. The following is an instance:—A medical man, of lax fibre, ruptured his tendo-Achilles seven years ago, and, in spite of the injury, walked about a few days afterwards; at the present time he walks about, dragging his leg after him, like a paralytic man, although the cicatrix is only a few lines long, and would be only considered as likely to produce any lameness in those motions which require forcible contraction of the calf. The injury and subsequent want of use have evidently have caused a loss of power in the calf, which, in his feeble condition, could not readily be restored. It is a remarkable circumstance, that when the tendo-Achilles unites in an imperfect manner after injury, the foot is not drawn up by the flexor muscles, but hangs like a loosely connected part, showing that the diminished irritability of such a mass as the calf of the leg exerts a weakening influence on the entire extremity. That any person should commence extension immediately after the operation, and attempt to restore the limb to its natural position, using, like Sartorius, a degree of violence which makes us shudder to think of, is neither necessary nor advisable."

"The immediate restoration of the limb in its natural position is not to be recommended, for by extension before the healing of the wound in the skin, the parts are liable to inflame or suppurate: by gradual extension, the contractility of the muscle, the tendons of which have been divided, is interrupted for a time, and restored by the stretching and motion of the parts when the foot is again used. In all my cases," adds Stromeyer, "of division of the tendo-Achilles, the use of the muscles of the calf has been completely restored. Dr. Weiss informs me that, at Paris, the use of the muscles of the calf is not always restored. This may probably depend on the immediate separation of the ends of the tendon, which does not prevent its healing, but hinders the restoration of the functions of the part; it is also possible that, by the extension of the

intervening substance, which, from immediate extension, is very thin, the cicatrix itself may be lacerated." The views of Stromeyer are, I believe, on the whole correct. I am of opinion, however, that the new substance will and does admit of sufficient extension to compensate for the greatest amount of shortening met with in any deformity; for I have repeatedly, in cases of talipes equinus, found the new connecting medium full two inches in length within three or four weeks following the operation, especially in those cases where there is no resistance in the joint, and where the foot admits of being rapidly brought into its normal position. Again, how often is it that, in fracture of the patella, or in rupture of its ligament, the new and permanent uniting medium is full three inches in length, sometimes more, and sufficiently strong itself, were it not that the muscle, from its greatly increased length, loses its power of action. I was lately consulted by a gentleman who, six months previously, had ruptured his ligamentum patella. He was kept at rest, and the patella held well in position for six weeks; at the end of that time he was allowed to use the limb. For the first few days he walked with comfort, feeling but little inconvenience; by degrees, however, he experienced great weakness, and found his knee-esp, to use his own expression, rising and getting high. No means were adopted to prevent it, and the uniting medium has become gradually elongated to the extent of two or three inches, through the constant extension kept up by the action of the rectus and crurus muscles: the new substance is firm and strong, and the patient is enabled to walk with ease on level ground, but is totally incapable of extending the leg sufficiently to walk up a steep hill, or up and down stairs, without, in ascending, drawing it after him step by step, and, in descending, placing it first on each step, and bringing its fellow down to it. I have not the slightest doubt that, had the extended position been maintained for three or four months, until the new matter had become consolidated, and had degenerated, so to speak, into a permanent cicatrix, that no ill consequences would have followed. It is true, as a general rule, that the cicatrix, after the cure is effected, measures but a few lines, oftentimes only a line, in the thickness, provided proper care has been taken during the treatment, which arises from the circumstance, that every new substance, after it has fulfilled the purpose for which it was generated, viz. the restorative process adopted by nature to remedy any wound or injury, loses its vascularity, except so far as is necessary for its individual vitality, contracts upon itself, and draws with it, if unrestrained, the part with which it is connected, as in the painful distortions so frequently

witnessed in burns on the neck and face. In the foot I have found the permanent cicatrix full two inches in length (after the operation for talipes equinus); and a worse distortion produced, viz. the talipes calcaneus valgus, where the foot was placed in position immediately after the operation, and kept for a long time in the flexed position: this position was not, however, maintained, except during the exercise of volition. The elongation in congenital cases, and also in non-congenital cases, of young subjects, is undoubtedly effected eventually at the cost of the contractility of the muscle, but not primarily; this is a secondary result, for no new uniting medium can by possibility possess the power of drawing down the muscle any more than the newly formed granulations following a burn can do; the cicatrix, as it contracts, certainly does so, but after the foot is brought into position, and hence the linear cicatrix. The force of the contraction of a cicatrix is sufficiently evident in the instances of burns alluded to, not only to draw down and overcome one muscle, but even a set of muscles—as the extensors of the head and neck, or of the arm, and other parts. I have had two opportunities of examining the condition of tendon (that had been operated upon during life) after death; the one was a boy about seven or eight years of age, in whom the tendo-Achilles was divided for complete talipes equinus, the heel being elevated to its full extent: he was of weak, delicate, and unhealthy constitution, and the foot was brought into position three or four weeks after the operation: the uniting medium was at that time nearly two inches in length, soft, yielding, and exceedingly weak. It gradually, however, strengthened, contracted upon itself, and became as strong, to all appearance, as the original tendon, nor could any irregularity or thickening be detected. Twelve months after the operation he was attacked with scarlet fever, of which he died. His father informed me of it, and offered to allow an examination. On examining it externally, no trace of its having been divided could be detected; it possessed the same prominent uninterrupted outline as its fellow; the point of puncture could with difficulty be detected. On removing the skin and cellular tissue, there was no evidence of a wound having been inflicted, no adhesions, thickening, or swelling, and on laying open the sheath the tendon presented one uniform and natural appearance, so much so, that one was almost led to doubt the possibility of its having been divided. I then made a longitudinal section, but could discover no alteration with the naked eye, except a sort of globular appearance in one spot, but not sufficiently differing from the tendon itself to make us positive. The other was a congenital case of talipes varus, in a child of eight months of age when

operated upon, and who died from whooping-cough and head affection eight months after the operation. The tendo-Achilles, the anterior and posterior tibial tendons, had been divided. The same perfection existed here, and, at the examination, no trace of any kind could be detected, in appearance or by sense of touch: I was fortunate enough to obtain the tendon, which you can examine for yourselves. That the division and reunion of the tendon acts on the vital properties of the muscle, and, by diminishing its irritability, lessens its contractile power, is to me doubtful, and will not apply, as far as my observation goes, to any permanent contractions, for in these cases we have no evidence whatever of irritability of the muscle existing at all. In spasmodic contractions, however, where the exciting cause still exists, it may have that effect, but of this I have seen no proof. If disconnecting the muscle and tendon, and allowing the former to contract upon itself, thus destroying altogether its power of control, be an evidence of this influence, well and good; but in those cases of spasmodic contractions where the division of the muscle has been effected, and the limb more easily held in position, yet, as the newly formed substance gains strength, the same irritability and spasmodic tendency exists upon any attempts to exercise the voluntary power; nor have I seen an exception to this. An old gentleman, seventy-two years of age, consulted me about a spasmodic contraction of his great toe, which, after walking a short distance, inconvenienced him so much, that he was willing to submit to any operation for relief. I first divided the long flexor in the sole of the foot, and for fourteen days he could walk without the contraction being produced, although he experienced the same sensation of contraction of the muscle. As soon as the new uniting medium was sufficiently strong, down went the toe as badly as ever. I then divided it beneath the first phalanx, which effectually prevented a return of it, but not in the slightest degree was he relieved from the sensation of spasm; nor can I understand upon what principle the irritability of a muscle can be relieved by a division of its tendons, as the nervous supply is from above, not below.

The debility arising in the case of the medical man mentioned by Stromeyer was caused, in my opinion, from too early use. The circumstance of the foot hanging like a loosely connected part, after imperfect union of the tendo-Achilles, arises in consequence of the balance of power being destroyed between the flexors and extensors; the flexors being weakened from want of the opposing power necessarily exercised during the time the gastrocnemius retained its natural condition, the foot, of course, would not remain flexed except during the exercise

of the will. It appears, therefore, that Delpsch and Stromeyer are both correct with regard to the condition of the new substance, and it is only a question of time whether the tendon be examined within a few weeks, or after the claustrix has become confirmed in its position.

Von Ammon (*De Physiologia Tenotomia*) gives the following account of the union of tendons:—When a tendon is divided a slight degree of pain occurs, but no spasm of the part. In a short time a gap is produced by the contraction of the divided tendon, the principal part of the contraction taking place in the part of the tendon above the division. This gap is soon filled up with blood, which, he says, chiefly flows from the upper end of the divided tendon. This blood soon coagulates, and in this process unites firmly with the surrounding parts, and more especially with the wounded surfaces of the tendon, the ends of the tendon presenting at this time an appearance as if they had been tied round with a thread. The next change consists in the effusion of coagulable lymph beneath the effused blood, from the surrounding tendon and adjacent parts; this lymph becoming soon marked with conical and thread-like streaks of a white colour, which extend from the two divided ends of the tendon, and seem to shade gradually into each other. This soft substance thus thrown out, instead of remaining as a pulpy semi-transparent mass, soon becomes connected into a structure which resembles, to a certain degree, the structure of tendon. This substance is not, however, true tendon in structure, although it exercises the same functions: on the surface and in smoothness it resembles tendon; but it differs from it in presenting, in its early stage, a substance of an udder colour, and of a more compact form, and afterwards presenting a more blue colour than real tendon. The motions of this new substance are more confined than those of real tendon, partly on account of its want of elasticity, and also from its adhesion to the surrounding parts. This new substance is formed in about fourteen days. It may not be uninteresting to lay before you the first case Delpsch operated upon, on the 9th of May, 1816, which is related with so much simplicity, truth, and candour. A magistrate of Montpellier consulted Delpsch about a congenital deformity in the foot of his son, a boy nine years of age. After a careful examination, Delpsch finding the resistance existed in the tendo-Achilles, and reasoning on the restorative process adopted by nature in case of rupture of that tendon, and of fracture of the patella, determined to make an attempt to cure the deformity by means of the division of the tendon, feeling satisfied that if the foot was brought into position,

and maintained by suitable support, the patient would be in a much better condition, although he might not possess the power of using the muscle of the calf. The operation is thus detailed:—The patient was laid horizontally on his face, so as to exhibit the parts of the leg containing the tendo-Achilles. "We," he says, "introduced the blade of a knife completely before the tendon, and caused it to pass entirely through from the internal to the external side of the leg, so as to divide the skin on both sides an inch in length, and with it the cellular tissue in front of the tendon. This instrument was then withdrawn, and replaced by a knife the end of which was convex, the direction in which it acted being from the front to the back of the tendon (our present mode of dividing it), which was thus divided transversely entirely through, without touching the skin which covered it. This portion of the operation was but slightly painful; and as soon as it was accomplished, we hastened to flex the foot, and found, with the greatest satisfaction, that no obstacle existed to prevent the axis of the foot from forming a right angle with the axis of the leg. Satisfied with this experiment, which convinced us that the first difficulty was overcome, we proceeded to apply the apparatus which we had prepared to fix the foot in the position in which it was held by the tendo-Achilles before the operation. With this view, the instrument was assisted by a linen bandage like a sling, which, taking its support from the ascending side-pieces, constantly pushed the heel forward. In this condition the two ends of the tendon appeared perfectly opposite, and in immediate contact, as well as could be perceived through the integuments. In order to keep the ends in position, to preserve them from the slightest motion, and also to prevent any swelling of the cellular tissue surrounding them, as well as to keep down inflammation, slips of adhesive plaster (which did not, however, at all tend to draw together the lips of the two small wounds) were used to fasten down pieces of lint on the point of section, causing a slight pressure upon it. The limb was afterwards placed upon a pillow, with the inner side upwards, the leg and thigh being bent. Thus each part being fixed in the position which it should occupy, the state of the case might any moment be examined without disturbing the apparatus. The patient was then put on a severe regimen, and allowed nothing but rice-pudding and veal-broth. The pain following the operation was very slight, and the patient would have slept well had not the excessive but very natural anxiety of Delpsch caused him to order an attendant to keep her hand constantly on the limb to prevent any hazardous movement. On the tenth day a

soft swelling was observed, which, on being pressed, discharged a certain quantity of matter from the wounds which had not united. This process enabled him to see that the two ends of the divided tendon were not separated from each other. On the twelfth day portions of sloughed tendon and matter came away, after which it proceeded favourably. Twenty days after the operation no interval could be perceived at the point of section, but a sort of narrowing or neck, which, he says, indicated that neither the breadth nor thickness had been preserved. On examining it on the twenty-eighth day, the narrow part of the tendon was found to occupy only a few lines in length, and to be influenced by the movement of the foot. Extension was now commenced, and for two days little pain was experienced, nor did the heel come down. This, he says, involved consequences so serious, as to lead them to seek diligently for the cause of such a phenomenon; when they discovered that the patient had loosened his straps (a circumstance, gentlemen, of no uncommon occurrence). Greater care was then taken, and the stretching kept up; upon an increase of which, pain was felt, but it did not interfere either with his appetite or rest. As the flexion proceeded, the foot was found to evert; and as the instrument was not capable of preventing this, splints were applied on both sides, so as to prevent any lateral deviation. Extension was reapplied, and from the pain which followed it was evident the machine was acting efficiently. The foot was greatly improved, and on examining the tendon it was clear that the two ends of the tendon were separated nearly an inch and a half. In a few days more the foot was bent to a right angle; but he adds, the use of the instrument was continued much longer, in order to keep the parts in position during the period required by nature to give to the intermediate substance all the solidity requisite. At the end of a month it presented an extension of two inches in length, and an insurmountable resistance prevented the flexion of the foot beyond a right angle. To enable the patient to walk, a kind of boot was contrived, with springs attached, suitable for propelling the foot forward and keeping it in position. The patient used his foot with excessive pleasure, and with all the confidence desirable. A temporary illness followed, but he says he now enjoys perfect health, and with the aid of a convenient apparatus, which we intend him to wear for several years, excites, by the ease and rapidity of his walk and movements, the astonishment and admiration of all those who knew his former distressing state of deformity.

I have, gentlemen, thought it right to give

you this case thus in detail; as it is full of interest, from being the first practical information we possess on the subject. It teaches us, besides, the reward of perseverance. Delpech had no ordinary difficulties to contend with, and yet he allowed none of those obstacles to prevent him from carrying out his views; on the contrary, he met with difficulties at every turn, but met them boldly, and has shown the world that deformity was no longer to continue invulnerable, but that it must succumb to the science of surgery; and in thus patiently, ingeniously, and triumphantly overcoming every impediment, he has laid the foundation of the new and successful treatment which we are at this moment carrying out. Delpech seems to have grasped the whole system, for he not only got the foot into position, but directed his attention most extraordinarily to maintain it so, proving how correct were his physiological views of the new uniting medium;—and his ordering a boot with the support attached, for his patient, is a circumstance of great importance, thus leaving nothing undone, nor to which we have as yet added in its principle.

To Stromeyer, however, belongs the exclusive credit of re-introducing it; for, strange as it may appear, none of Delpech's countrymen took it up; neither, as you are well aware, did any one in this country. Dr. Stromeyer, of Hanover, at length directed his attention to the subject, and extended it to deformities in general, with success. It is now little more than seven years since my late colleague, Dr. Little, having witnessed the treatment of Stromeyer, introduced it into this country; having also, on his way back from Hanover, visited Berlin, where Professor Dieffenbach operated on an immense number of cases of every variety, dividing every muscle that appeared contracted, and has applied the operation also to the reduction of dislocation. He has only mentioned the division of the posterior tibial tendon in two cases, whereas we find it necessary in almost every case of talipes varus, from its extensive insertion, and the great power it possesses of rotating the foot inwards, in consequence of the leverage it possesses from passing under the inner malleolus. It was, however, never attempted, that I am aware of, in children under twelve months old, until I invented a stilette and canula, with the blunt-pointed knife, which enabled me to divide the muscle in infants without risk of puncturing the posterior tibial artery. The complete division of the artery is not, from our experience, of any moment; it has been frequently done, and must with the greatest precaution occasionally occur. Not so, however, a puncture of the artery, two cases of which have occurred: in both false aneu-

ism was the result, and in both was it necessary to cut down upon and to tie the vessel. The first was a puncture of the posterior tibial, the other of the internal plantar artery, in a boy 11 years of age. Since the opening of the Institution more than two thousand cases, embracing every variety and complication of deformity, have presented themselves; and, I say it with pride, our success has equalled our most sanguine expectations.

The term *special* has been applied to the peculiar objects of this and of other institutions devoted to one purpose: if it conveyed an impression only of that kind, I should not have noticed it, but this term too often leads to the conclusion that those connected with such institutions confine themselves to the study of one department of the science; but, gentlemen, because we as surgeons choose to adopt the improvements made in the profession of which we are members, are we to be designated by the opprobrious term of specialists, and thus, by implication, to be excluded from surgery in general? if such were the consequence, much as I might deplore the ignorance or bigotry which caused it, I would not belong to this institution another hour: I give place to none in my anxiety to follow surgery as a science, or to uphold it in the position it justly takes in the rank of the learned professions, and however inferior I may be to my professional brethren in ability, I yield to none in love for the profession, or in anxiety to preserve it inviolate as it ought to be: "an honorable, an intellectual, a noble occupation," my most strenuous efforts will ever be directed to cultivate and cherish the good opinion of its members. The objects of this charity call into exercise our anatomical, physiological, and surgical knowledge; they embrace the muscular, the osseous, and ligamentous tissues of the whole body, as well as the skin itself; the cerebrum and spinal marrow but too frequently are causes, and, with the exception of congenital cases, are very general causes, of the deformities which present themselves; and many cases are occasioned by diseases of the bones and joints, and parts surrounding them: if, then, the term *special* can be applied, I can only say it is a specialty embracing the study of the whole body. This branch of surgery calls into exercise, as I have just observed, our anatomical, physiological, and surgical knowledge; and is not the mechanical treatment in accordance with the treatment of dislocations and fractures? I believe the knowledge of the treatment of deformities scientifically will be the means of improving mechanical surgery in general. A case was related a few weeks since, where the tendo-Achilles was divided to enable the surgeon to reduce a dislocated ankle. Again, let us go to the

causes of congenital deformities: some are at present inclined to attribute them to a mental impression, generally a sudden one, received by the mother during pregnancy; but the evidence is far from being conclusive; for it oftentimes happens that the mother can assign no cause; in other cases the deformity appears hereditary, and I know of one instance where a family of eight children had double varus, and the parents refused to have any thing done for fear of destroying their uniformity.

In non-congenital cases teething, worms, and irritation of the spinal chord, are frequent causes. Certain occupations, such as much standing, or carrying heavy loads: position also may be regarded as a cause, especially in lateral curvature of the spine, knocked-knees, &c. and disease of the bones themselves in antero-posterior curvature; muscular action in rachitis, as the immediate and insufficient nourishment, or badly assimilated food, as the remote cause, injuries also of various kinds to the spine, bones, &c.: but occasionally we are at a loss to discover any cause, the deformity coming on insensibly, whilst the patient is apparently in perfect health. Again, deformities themselves vary as much as their causes; the same deformity in both feet will rarely yield to treatment as rapidly in the one foot as in the other; and even in infants one case will present comparatively little difficulty, whilst another, precisely analogous in appearance, will require the greatest caution and perseverance, and sometimes a long time to effect the cure. Thus, gentlemen, you will perceive that there is abundance of mental occupation in the treatment of deformities, but most especially in the investigation of their causes; for, in my opinion, the non-congenital are by far the most painful and severe in their consequences, involving but too frequently paralysis of the moving powers themselves. These cases, if attended to at their commencement, might certainly be relieved and prevented, but it often unfortunately happens that there is little interference with the general health; the deformity, as in the foot, for instance, coming on insidiously, no attention is paid to the circumstance; a weakness, as it is termed, of the ankle is felt, and the foot deviates occasionally from its natural position: the fears of the parents are then excited, and they consult their medical attendant, who consoles them with the mistaken notion that the child "will grow out of it;" and thus the foundation is laid for a permanent deformity, or at all events a permanent weakness, of one or both limbs, which may involve their being disabled for life.

Gentlemen, it is our privilege to be placed in the position of administering relief to those who have hitherto regarded relief as

hopeless; and if there be one encouragement greater than another, it is the inexpressible happiness of witnessing the success attending our efforts, on the one hand, and the gratitude evinced by those emancipated, if I may so express myself, from perpetual bondage, on the other. This applies with peculiar force to the deformed poor, who have been doomed to drag out a miserable existence in the workhouse, shut out (to use the words of the poet) "from the common air, and common use of their own limbs." We have had, since the opening of the institution, patients sent from workhouses whose deformities arose from injuries to the spine, totally unable to move without crutches, but who have walked out of the house, and been enabled to resume their occupation.

It is an unspeakable gratification to be the instrument of dispensing these blessings. But, gentlemen, we have a still more exalted object in view; viz. to extend by every means in our power the knowledge of this branch of surgery to our professional brethren, and thus to make relief universal throughout the empire.

ON THE

RETENTION OF UREA IN THE BLOOD, IN CASES OF FEVER.

By MICHAEL W. TAYLOR, M.D. Edin.

(For the Medical Gazette.)

So many admirable papers and descriptions have been published illustrative of the peculiar type of fever, which has been described in this part of the country as the prevailing epidemic of the last twelve months, and as that disease has now almost, and in some quarters entirely, ceased to exist, any further attempt to illustrate its peculiarities might perhaps be deemed unseasonable. However, the case presently to be related, selected, on account of the unusual phenomena attending it, from among others of a similar nature, affords, I think, a good example of one of the most interesting facts connected with the pathology of the recent epidemic, viz. the occurrence of retention of urea in the blood. The liability to this occurrence not only in the course of this modification of fever, or rather this specific form of fever, but also in typhus, particularly towards its later stages, and in both cases independent of any specific or organic disease of the kidney, has been pretty fully made

out, from the facts elicited from the observations pursued in Professor Henderson's clinical wards, during the last winter.* But though the liability to this occurrence is now very generally received as a standard principle in the pathology of these fevers, and must become of extreme importance in relation to their treatment, the paucity of the details yet preferred in regard to it has induced me to offer the following case as an illustration of this disorder of the blood, and to append to it such remarks as the consideration of the subject may seem to demand.

CASE.—Janet Thomson, æt. 24; admitted March 12th, 1844. Reported on 13th. Lived in Leith. Is a stout, plethoric young woman, unmarried, but of irregular habits. Seems to have been seized on the 7th inst with shivering, pain of head, and pain in the back and limbs; states that she felt languid and indisposed for a day or two previously. States that she has seen no one ill with fever, but that in the house in which she was lodging there were several persons who had some time previously been affected with what she believes to have been the common epidemic fever.

Sweated a good deal last night, and is at present perspiring freely; does not think she has sweated so much before during her illness. Pulse 80, soft, of fair size. Pain of head, which was severe yesterday, entirely gone. Complaints of some stiffness and pain in the arm and shoulder. Bowels open from medicine taken last night. Tongue moist, and covered with a white fur. Has not passed urine since admission at noon yesterday, previous to which it was in good quantity. There is no distension of the hypogastrium, nor dulness on percussion over that region. Complaints of a feeling of heaviness and drowsiness, every now and then falling asleep, and awaking in a short time with a start, and a sensation as if she were falling from the bed. There is some dimness and indistinctness of vision, giddiness, and a feeling of heaviness over the eyes; a greater slowness and hesitation of utterance than yesterday. Little confusion of head, as she answers intelligently questions respecting her present con-

* Dr. Henderson, Edin. Med. and Surg. Journ. vol. ix.; The author, in *Scottish Medical Gazette*, Feb. 1844.

dition, though she cannot describe so precisely as before some of her previous symptoms.

R. Nitratis Potasse, ʒss.; Liquor. Acet. Ammoniac, ʒiv. M. Sumat. ʒss. 2dā quaque horā.

March 14th.—Pulse 68, somewhat irregular in its beats. Began yesterday half an hour after having taken the first dose of the medicine. At 7 o'clock P.M. she had made six or eight ounces of high-coloured urine. The whole quantity in 24 hours is 34 ounces. Sp. gr. 1020, colour reddish brown, destitute of deposit; no precipitate by heat or nitric acid. Has sweated a good deal since visit yesterday; feels much lighter; the feeling of languor, drowsiness, and uneasiness in the head, is gone. Skin cool and moist; tongue moist and furred.

Omitatur Mistura.

15th.—Had some slight shivering this morning. Skin hot and dry; pulse 68. Urine 24 ounces since yesterday; sp. gr. 1024.

2dā.—Has continued feverish since last report, but with no bad symptoms. Pulse 120. Skin hot and dry; has an oppressed look. No stool to-day, but bowels open freely before. No headache.

Hab. Liquor. Ammoniac Acetatis et Nitratis Potasse.

24th.—Pulse 120, of fair strength. Skin hot and dry. Countenance has much of a sallow expression. Pupils pretty large and equal. No decided difference between the two sides of face, when the features are at rest, but a very decided obliquity of the mouth, and protrusion of the tongue to the right side, when desired to put it out, the left angle of the mouth being drawn out at the same time. On speaking, the left side of the mouth alone moves. She is not insensible, but her intelligence is obscure. She moves the right arm freely enough, but cannot squeeze with it so strongly as with the left. Moves the right leg, but whether as well as the left cannot be determined. There is a bright red patch, and a series of others downwards on epigastrium and abdomen; a pale-coloured weal occupies the centre of the largest, and a similar spot, with a weal, exists at the carpal extremity of left thumb. A superficial slough on the left heel, and

an ecchymotic spot on the right instep. Tongue dry, and darkly furred. Urine has not been preserved, but is stated to be in small quantity.

Abradatur Capillitium; R Nitratis Potasse, Siss., Aquæ, ʒx. solve. Sumat. ʒj. 2dā quaque horā.

25th.—Pulse 116, of good strength. The hemiplegia of the face remains as before. Tongue dry; several stools. Urine said to be in good quantity, but not kept. On the left foot the upper surface of the little toe is occupied by a bulla of blood; another between that toe and the next. The spots on the epigastrium are not so large; that upon the right thumb is converted into a straw-coloured bulla. Intelligence, pupils, &c. as before.

Continuatur Mistura.

26th.—Pulse 104, of good strength. Right cheek as before; right pupil smaller than the left, but not contracted. Tongue dry, but clean. Pus in the bulla on right thumb. The largest bulla on left foot has emptied itself of blood, and the part is healthy below. The vibices are mending. Urine in moderate quantity.

Habeat Pulv. Jalap. Comp. ʒj.

27th.—Was observed in the morning in a state of stupor, being incapable of observing or replying. She was directed by one of the clerks of the house to be cupped about an hour ago. Pulse, at present, 150, very feeble. Is incapable of comprehending or replying to questions. The right pupil is considerably dilated. No effect is produced on the eyelids on thrusting the hand towards the eye; the left pupil is smaller, not contracted, and she winks on thrusting the finger towards the eye. Even irritation of the conjunctiva produces comparatively little effect on right side. No motion of the right arm is produced by irritating it, and it is quite in a state of resolution; pricking it, however, produces an expression of pain. Above the inner condyle of the right femur, and below the inner aspect of left knee, parts which are said to have been lying in contact, there are spots of corresponding size of two inches long, by an inch and a quarter broad, consisting of red discolouration, containing a deep purple patch, nearly two-thirds of size of whole spot; around the redness there is a halo of a pale

lemon colour. A scanty eruption of sudamina on the belly. A large bulla, containing apparently blood, has formed on outside of left foot. Urine passed in bed; its quantity cannot be ascertained, but judged to be not more than a few ounces.

Haust. Spiritus.

28th.—Died last night at 11 o'clock. No inspection could be obtained.

REMARKS.—It appears that this woman, after exposure to the contagion of the epidemic fever, was seized, on the 7th inst., with the usual symptoms of that disorder; and that on the seventh night thereafter the exacerbatio critica commenced, which terminated as usual with a copious perspiration and total cessation of the febrile state. Coincident with the occurrence of the crisis there appeared a series of symptoms which must often have presented themselves to the attention of those who have observed accurately this disease; viz. a peculiar and very manifest cerebral oppression, indicated by a degree of drowsiness, lethargy, vertigo, preternatural slowness of speech, slight confusion of mind, and, what I have very frequently noticed in this, and those other diseases in which the blood is prone to become similarly empoisoned, viz. dimness and indistinctness of vision, and sometimes spectral illusions, often apparently similar to those accompanying that condition of the blood resulting from excessive or repeated indulgence in strong liquors. Though there was no opportunity afforded, at this period of the disease, of confirming our suspicions by an analysis of the blood, yet I think, from what we have observed in other cases of the same description, and from what we know of its effects, that there can be no doubt of the propriety of referring these symptoms to the retention and circulation of urea in the blood, and its poisonous influence on the nervous system, particularly as, coincident with these symptoms, there had been an absolute suppression of the urinary excretion of at least thirty hours' duration. However, the restoration of the excretion being effected by the administration of a vigorous diuretic, these symptoms, which I have no doubt would otherwise have speedily become alarming, gradually subsided.

After an apyretic interval of two or three days, the fever recurred; on what precise day was not determined, but about the time at which this second febrile paroxysm should have remitted, and the crisis occurred, there appeared a train of symptoms of a very peculiar and alarming description. The febrile state still continued, the pulse still maintained its morbid frequency, the aspect acquired a sottish typhoid expression, which it did not possess before, a degree of torpor and obscurity of intelligence supervened, and there appeared decided symptoms of general hemiplegia of the right side of the body. Besides, a further complication of the case made itself manifest by the appearance, on different parts of the surface, of irregular bright red ecchymotic spots, vibices, and bullæ, or effusions of blood and seropurulent matter beneath the cuticle, some of such effusions apparently being produced on spots on which slight pressure had been made, others occurring spontaneously. This state, after continuing for three days, advanced to complete stupor and paralysis, and the patient died comatose, and with a very frequent and feeble pulse, on the night of the 27th, without ever having had convulsions. The urine throughout this period seems to have been passed but in small quantity.

In the hope of finding some explanation of this hæmorrhagic tendency in some alteration in the proportion of the salts of the blood, which ought to have been the case in accordance with the doctrines of Stevens and others, I subjected to a very careful analysis 1000 grains of the serum obtained by the cupping performed on the morning preceding the final issue of the case: the result of which chemical analysis was the following:—

Water	901.03
Albumen	84.39
Soluble	{	Decomposable by	heat	.	4.42	9.69
		Not decomposable by heat		.		
Salts					5.27	
Insoluble salts	2.8
Urea, fatty, and extractive matter	2.07
						1000.58.

According to M. Lecanu, 1000 grains of the serum of the blood of women contain—

	Water.	Albumen.	Soluble salts and extractive matter.
Maximum	921-311	84-490	14-350
Minimum	903-631	67-990	9-080
Mean of ten analyses	909-943	78-903	11-153.

The condition of the serum, as the above analysis shows that there was no material transgression in the proportion of its several ingredients beyond the physiological limits of each, cannot afford any explanation of the cause on which the remarkable tendency to extravasation depended. The blood drawn by the cupping possessed its normal scarlet hue, coagulated as usual, and the clots, though somewhat voluminous in proportion to the serum, did not appear to be much deficient in firmness; hence it is probable that there was neither any defect in quantity of the fibrin, nor a diminished attraction of aggregation in that fibrin. But as no special examination was pursued beyond that of the serum, I am not prepared to state to what particular alteration in the constitution or qualities of the solids of the blood this hemorrhagic tendency was owing. Be that as it may, in the course of the analysis of the serum it was found that urea existed in it in large quantity; so abundant indeed was it, that on the addition of nitric acid to the aqueous solution of the alcoholic extract, it was speedily converted into a solid crystalline mass, consisting of the eminently characteristic scales of nitrate of urea. In consequence of this circumstance I consider the details of this case as worthy of notice; not that I wish to assert more than the probability of the hemiplegic affection, and finally death, having been owing to the retention in the blood of so large a quantity of urea, which we cannot suppose to have circulated in the brain without having exerted on it its poisonous influence to an injurious extent, being aware of the possibility of the hemorrhagic tendency, which was so abundantly manifested on the surface, having extended itself to the membranes of the brain, and even to the cerebral capillaries themselves. However, as an opportunity of proving the actual state of the case by dissection was not afforded, I conceive that I am

justified in hazarding the former conjecture.

I am not aware of any observations to prove what influence the presence of urea in the blood may have in producing hemiplegia, but I think that such an action may not be unlikely, from what we know of the various derangements of the nervous system which are so prone to occur in the course of Bright's disease of the kidney, in which there is such a proclivity to retention of urea. The headaches, giddiness, transient imperfections of sense and of memory, the quiet stupor, the obstinate muscular pains (generally described as rheumatic or neuralgic), the transient paralytic affections, which often attend this disease, and what may be called its natural mode of termination, viz., by way of coma and convulsions, are no doubt all dependent on the poisonous influence of urea on the nervous system. Such cases, before the researches of Dr. Bright and others, were all set down in the class of simple apoplexies, no effusion of blood or other perceptible morbid appearance shewing itself in the brain, the apoplectic state being referred to the pressure exerted on the cerebral substance by an increased propulsion of blood upon it or transmission through it. But supposing the condition of apoplexy to have been produced previous to the impregnation of the blood with urea, the question may then be mooted, whether such a lesion of the nervous centres as that caused by hæmorrhage within the cranium, can so affect the secreting faculty of the kidney as to hinder the free elimination of urea from the blood. The examination of the blood in a series of cases of apoplexy would determine this point, the possibility of which seems to me not to be visionary, from all that we at present know of the influence of the nerves on secretion. The experiments of Krimer, at any rate, prove, that injuries to the brain and spinal cord, if they do not produce entire suspension of the urinary excretion, alter materially its characters. This physiologist found, that after division of the spinal cord in the dorsal or lumbar region, the urine became limpid, like water, of low specific gravity, with an unnaturally small proportion of its peculiar animal

matters : after division of the medulla oblongata, the secretion of urine was entirely and instantaneously arrested,—a fact which was previously observed by Sir B. Brodie, in the course of his experiments on the influence of the brain on the action of the heart, published in the *Phil. Trans.* 1811. Drs. Müller and Piepers also found that destruction or division of the renal nerves was in most cases speedily followed by a complete suspension of the urinary excretion. These experiments show that we are not to regard, as some have done, the kidneys as mere mechanical filters to the system, but how much they are under the influence of the nervous centres. The influence of emotions and other mental impressions on the secretion of urine may be adduced as an additional illustration of the same fact ; and it is in nervous subjects, particularly hysterical females, that those remarkable cases of vicarious secretion of urine, independent of disease of the kidney, have been observed.

In consequence of being precluded from an examination of the state of the internal organ after death, these remarks can only be considered as hypothetical, but whatever lesions may have existed, there can be no doubt that the phenomenon to which our notice is at present particularly directed, viz. the existence of so considerable an amount of urea in the blood, must have materially promoted, or perhaps accelerated, the unfortunate issue of the case.

The immediate cause of retention of urea in the blood, in cases of fever generally, has not yet been precisely determined. Urea being for the most part derived from the decomposition of the extreme tissues, and as during the course of a fever the transformation of these tissues is believed to be effected with increased rapidity, an excessive formation of that principle will result, and if from any cause the organs by which it is naturally eliminated from the system be temporarily embarrassed, whether by a slight mechanical obstacle to secretion in them, or by excessive secretion elsewhere causing derivation from them, this deleterious product, urea, will accumulate in the blood, and act injuriously on the brain, which had already encountered the oppression arising from the poison of the fever itself.

In the recent epidemic fever, certainly, the symptoms of this affection of the blood seemed generally to coincide with the partial suppression of urine which so often followed the critical sweat with which the fever subsided. I have observed, that generally during the maintenance of the febrile paroxysm, the urine was voided in good quantity, often amounting to 40, 50, or 60 ounces during 24 hours, and containing an amount of urea, much above that which is esteemed by M. Becquerel as the daily average in a state of health : and that during the declension of the fever, and in the apyretic interval, it was usually diminished, sometimes below a third of the natural quantity, or absolutely suppressed for a certain period, the amount of urea in the former case undergoing a correspondent diminution.

In this fever, then, it is probable that the excessive spontaneous sweats which occur during the critical period, and endure for some hours, interfere so materially with the healthy action of the kidney, that the essential elements of urine, the production of which was previously going on with increased rapidity, no longer obtaining a free means of escape from the system, collect in the blood, and act as a poison to the brain. The operation of a similar cause is exemplified in spasmodic cholera ; the copious alvine discharges in that disease check most of the other excretions, and amongst the rest that of the urine, the essential element of which, viz. urea, consequently accumulates in the blood, where its presence has been demonstrated by Dr. O'Shaughnessy, Simon, and Rainey of Glasgow.

These remarks are understood to refer merely to the recent epidemic fever, and not to typhus, in which disease no such critical evacuations are seen, but in the later stages of which I am confident, from a few observations, that retention of urea occasionally occurs.*

Edinburgh, Aug. 1844.

* One example of this disease, in which the patient died comatose and with convulsions, and in which urea was found in the blood, was published by the author in the *Scottish and North of England Med. Gazette*, February, 1844.

ON
A NEW CRANIOSCOPY,

UPON A SCIENTIFIC FOUNDATION :

*A Lecture delivered at Leipzig, on the 3d of
February, 1844,*

By DR. C. G. CARUS,
Medical Privy Counsellor, and Physician in
Ordinary to His Majesty the King of
Saxony, &c. &c.

TRANSLATED FROM THE GERMAN,

By J. C. H. FERNUND, M.D.

[Concluded from p. 754.]

(For the *London Medical Gazette*.)

AFTER these observations on the best mode to be adopted for the purpose of expressing by figures peculiarities in the structure of a skull, I proceed to answer the question above mentioned, namely, what the indications are of the psychical peculiarities in different individuals, which might be taken from a comparison of the different structure of their heads; and principally the three cranial vertebræ, founding, at the same time, these important indications on a thoroughly scientific basis.

I comprehend the answer to this question under the few following heads, which must not be expected to be more than a general sketch; for much must remain here unnoticed, and much more must be expected from the further progress of this infant science.

I. A fine well-formed skull, properly arched on all sides, and sufficiently roomy in its frontal region especially—the measurement, for example, from the ear to the highest point of the front being 4" 10" to 5" 2", or 5" 3", to the highest point in the middle cranium 5" 2" to 5" 5", to the highest point in the posterior cranium 3" 6" to 3" 8", with corresponding length and width of each vertebra—bespeaks, like a large and regularly-developed brain, a good and powerfully organized psychical capacity for perception, feeling, and will.

II. A skull, stunted in growth, and deficient especially in the development of the frontal arch—the measurement of the height of the anterior vertebra being 3" 6" to 3" 10", of that of the middle cranium only 4", and of that of the occiput only 2" 6", with corresponding length and width of all the three vertebræ—indicates, with a badly-developed brain, a very unfortunate and

[* L. c. 4 lin. 10 lines, or 12ths of an inch.—Ed.]

most unfavourable psychical capacity for perception, feeling, and will; and any considerable malformation of this kind will be inseparably found connected with idiotism or weakness of mind.

III. In a similar manner will any superior development of the psychical faculties be excluded from a skull which is much enlarged beyond the ordinary size by dropsical effusion in the brain.

Should, however, the cerebral substance be but little impaired, a moderate degree of intellectual development may be possible, and does occasionally occur.

IV. In those infinitely various and intermediate forms of the skull, which neither reach the scale of a perfect, grand, and harmonious skull, nor come under that which is designated as one extraordinarily stunted and of a hydrocephalic nature, we shall have to ascertain, by comparing the three vertebræ one with another, which, or how many of them, possess a development regular, perfect, and beautiful, and which a development stunted, irregular, and deficient in beauty; and from this point we shall always be in a condition to arrive at some well-grounded conclusion on the predominant capacity of psychical life of an especial individuality, as regards the faculty of perception, the sphere of the feelings, the impulse of the will.

Here those combinations which are most remarkable are easily pointed out. They become, in fact, self-evident. Thus, for instance, we find that in the skull of the negro the frontal region is restricted, the middle cranium of only moderate size, but the occiput is strong and powerfully developed, and we conclude, therefore, an individuality of narrow and limited intellect, no very comprehensive feelings, but with a faculty of will eminently developed, and combined with great muscular vigour. When, on the contrary, we find the frontal cranium (forehead) fully developed, but the middle and posterior cranial vertebra very inferior in size, we may suppose that we have before us an individual to whom might be applied the term of "a mere man of intellect" (ein Verstandesmensch), one without any considerable share of feelings and energy, or in whom, perhaps, such capacities might be entirely wanting.

V. In making use of the above method of measuring, for the purpose of obtaining a knowledge of the different forms of head, it will be of importance to distinguish well from the original form, (a,) any prominences or depressions of the skull, either the result of accident or the effect of disease; (b,) any forcible compressions of the head, as is met with in many American tribes; and (c,) neither to forget the various degrees of thickness of the cranial bones, nor the difference in quality or consistence of the brain itself.

VI. Lastly, it must be granted that scientific craniology is wholly unable to prove any original capacity either for moral good or moral evil. If it were, as that abstruse phrenology founded by the so-called followers of Gall would assert, that there are distinct and separate organs of thieving, destructiveness, and secretiveness, and another distinct organ of conscience, truly the idea of man's liberty would be nothing more than an absurdity; and the murderer or thief who possessed the first named organs, but was deprived of the last, would stand justified before his earthly and heavenly judge.

These errors are entirely excluded from a craniology founded on scientific principles. Conscience, the moral feelings, are the real emanations of the Deity, felt by any man who is awake to consciousness of himself; and a person of feeble psychical powers—the negro, for instance, who is of inferior intellect—can, if he only listens to that inward voice, be as good and as virtuous, as the man of great psychical capacities can become erring and wicked if this inward monitor be neglected by him.

Nevertheless will the true craniology prove of great practical service in the administration of criminal justice; and some hints on this subject were, in fact, laid down by me in the *Journal of Medical District Officers* (2d section).

It is true, an individual of little sensibility and very small intellect, but with a strong inciting desire and will, can easily render himself liable to commit crimes of any kind—crimes to which an individual of superior intellect will not fall a victim; for the same intellect will tell him that by the commission of crime he will render himself unhappy. And it is a fact that the forms of skull which are usually met with in criminals are very unfavourable, a circum-

stance which, at all events, deserves the consideration of the judge, and calls strongly both for pity and for mercy. With such feelings should society regard the criminal; and if punishment cannot be entirely suspended, it should be awarded, not with feelings of vengeance, but as a means of amelioration and moral improvement.

In order to illustrate better the above six facts, I add here, by way of example, the measurement of four different heads:

1. That of a nobly formed male skull.
2. A male skull of inferior type.
3. A well formed female skull.
4. A female skull of feeble development.

Let us take for number 1 the skull of Schiller, the measurement of which is as follows:

1. *Frontal cranium.*

Height 5"
Width 4" 8"
Length 4" 8"

2. *Middle cranium.*

Height 5" 4"
Width 5" 10"
Length 4" 8"

3. *Posterior cranium.*

Height 3" 7"
Width 4"
Length 3" 7"

Let us compare with Schiller's skull that of a Negro slave:—

1. *Frontal cranium.*

Height 4" 6"
Width 3" 10"
Length 4" 2"

2. *Middle cranium.*

Height 4" 7"
Width 4" 6"
Length 4" 2"

3. *Occiput.*

Height 4"
Width 3" 2"
Length 3" 5"

The measurement of the skull of a celebrated actress and singer:—

1. *Frontal cranium.*

Height 4" 8"
Width 4" 2"

The length of it, as in that of the following case, could not be ascertained,

as the examination was made during life.

2. *Middle cranium.*

Height 5"
Width 5" 6"

3. *Occiput.*

Height 3" 11"
Width 3" 2"

And, lastly, the measurement of the skull of a complete idiot girl of 22 years:—

1. *Frontal cranium.*

Height 3" 3"
Width 3" 3"

2. *Middle cranium.*

Height 3" 11"
Width 3" 9"

3. *Occiput.*

Height 2" 8"
Width 2" 11"

We observe that, in Schiller's skull, the regions of perception, feeling, and will, are developed in perfect harmony one with another, and that the two first are especially striking and prominent. The proportions, therefore, must be considered favourable throughout.

In the Negro's skull we find the two first regions, namely that of intellect and feeling, in a very low state of development; while the region of desire and will surpasses, as regards its height, that of Schiller.

In like manner the female idiot shews a general inferiority of all the measures of the skull, while even the other favourable specimen of the female skull remains much in arrear when compared with that of a well-formed man.

We must here again bring to mind the great care and circumspection necessary in taking these measurements, if we wish to obtain any correct result from them. It would approach to an absurdity if we were to look at these measures as decisive by themselves, absolutely, without bearing in mind that they always must be considered in their relation to the form of the whole body, and that we must never lose sight of any disease which might have exerted some influence over them. If we neglect this precaution we run the risk of mistaking a skull which is enlarged by dropsical disease for that of a great and learned man, or of

believing any one two degrees wiser than his neighbour, simply in consequence of his frontal cranium being two lines higher than usual.

For this reason no other than a scientific anthropologist and physician ought to consider craniology as belonging to their sphere, and the craniometer handled by an ignorant man must, according to the words of Oken, become as ridiculous as the gypsy-like touch of the skull's prominences instituted by phrenological dilettanti.

I give myself up to the fair hope that I have succeeded in giving a general view of what may be called a scientific craniology. I must refer those who feel inclined to follow the matter any further to my "System of Physiology," vol. iii.; to my "Elementary Principles of a New and Scientific Craniology" (Stuttgart, 1841); and to an article on Scientific Craniology, inserted in Müller's Archives for Physiology, 1843, 2d sect.; and, lastly, to my "Atlas of Craniology," 1843, sect. 1.

I must yet direct attention to two other points:—

1. To the question whether the dimensions of the different regions of the skull and brain, taken each separately, have any different physical meaning; and

2. To the relation which exists between some particular provinces of the skull and the development of the great organs of the senses.

With respect to the first question, I would ask whether it be the same that some part of the brain and the corresponding cranial vertebra extends itself more in height, width, or length?

I would venture to say *a priori* that it cannot possibly be without some meaning; but the difficulty is to say what tendency is predominant. I cannot enter here any further, and much is left for more minute inquiry and comparison; but one thing I wish to be understood, namely, that if the formation of each of the cerebral substances proceeds from a simple middle, the divergence towards both sides can be regarded as the tendency to the formation of a well-balancing (reflecting) analytical mind, and that hereby the necessity is apparent of the frontal vertebra extending itself more in width, and, finally, that the same disposition which creates in the cerebral substance greater power of reflection, will have

some effect on the psychical life of the corresponding region.

We learn, for instance, from experience, that persons who are possessed of great analytical and philosophical power of intellect are also possessed of a frontal cranium of great width; and again, that persons with plain and simple intellect, the sphere of which is directed more towards the study of material objects, have a frontal cranium of considerable height. I hope this is a hint sufficient to shew how facts of this kind are to be understood, and how the subject in question can be entered into more minutely.

As regards the other point, namely the relation of the skull to the great organs of sense, it must be known that the organs of sight and hearing especially are themselves immediate continuations of the cerebral substance, and that all the impressions conveyed to the psyche by these two channels are of so much importance for the whole development of psychical life, that, if a man were deprived of these two senses from his very birth, to a moral certainty every chance of acquiring superiority in psychical life would be denied him. The action of these two senses upon the psyche is very different; and very ably was it remarked by Oken, that, through his eyes, man enters into the world; through the organ of hearing the world enters into man.

A strong prominent eye gives to the brute creation, as also to man, a character somewhat quick and courageous, or bold, one which sinks well into its objects; a strong prominence of the organ of hearing gives the idea of a retiring character, one brooding in itself and fearful.

How far, then, the development of these great sensuous organs contributes to the influence by which the skull leaves traces of its formation, must likewise be considered by craniology as diffusing some light on the peculiarities of the psyche.

Now the structure of the acoustic organs is visible in the skull by the formation of the temporal bones, or, as it can be termed, the first intermediate bone of the skull (os triquetrum); and the structure of the eyes is expressed in the formation of those osseous cavities called the orbits. Animals which enjoy a good sense of hearing, but are almost

sightless, as the mole for instance, are provided with a strong and broad auricular vertebra, but have indeed no peculiar orbit, the head being rather narrow in that region. Animals, on the contrary, with large eyes, and a proportionally inferior sense of hearing, as, for example, birds of prey, have very large and wide orbits, but are narrowed about the region of the ear.

In order to learn also something from the measurement of these parts of the skull, I would advise, in taking the measures of an individual, to add that of the width of the orbits as well as that of the temporal region, just above the ears, and there can be no doubt that, in these measures also, much will be found speaking to the character of the individual examined.

Persons with a prominent faculty of hearing, given to music, the study of languages, and at the same time timid and with a disposition towards a retiring life, usually shew greater width in the auricular region; while persons with an ascendancy in the sense of sight, devoted to the art of painting, to acute discrimination of localities, combined with a good deal of courage in their dealings, have mostly an orbital region of great width: and here, also, is much room left for further instructive observations and comparisons.

Enough of these remarks; and at the conclusion I think it will be of some interest to add something which refers to the results obtained by me from this new craniology up to the present time. Five years ago I first became awake to the light of a new craniology; and from that time I have profited by every possible opportunity, and submitted to the above mode of measuring the forms of heads of most different characters: I have also succeeded in obtaining a collection of skulls and casts, which is not very large in number, but is not the less valuable to me. In all the measures which I have taken I have seen the views above stated amply confirmed in their substance, and I have only to refer here to the tables before me.

1. In men with so scantily developed frontal vertebra (a front, for instance, which was below 4" 6" in height, and under 4" in width) I never found any considerable degree of intellectual power; but—

2. In a whole series of indivi-

duals with great powers of intellect I constantly found the frontal vertebra of considerable size (a height of 5" to 5" 3", or 6", and a width of 4" 6" to 5"). Of learned men I will only mention the names of Kant, Ehrenberg, Purkinje, Retzius, Raumer; of statesmen, the intriguing Talleyrand and von Lindennau; of artists, Rauch (5" 4" height, 4" 7" width), Bendemann, Thorwaldsen (5" 2" height, and 7" 8" width), and Godt. Schadow; of poets the names of Schiller, Goethe, Tieck, in all of whom the development of the frontal cranium was very considerable. I met with a very small frontal vertebra, by way of exception, in the natural philosopher Nobili, the height of which was 4" 6", and the width 4" 4"; but in this case the whole skull was of extremely fine structure, and the bones constituting it, especially that of the front, were very thin, the upper part of the orbits very delicately organised and almost transparent; the width of the auricular vertebra was also very considerable (5" 6").

3. From a series of measurements taken from the heads of very interesting and talented women, I never could find one frontal vertebra of a height equal to that of distinguished men, 4" 11" being the utmost I have met with; and this was the case with Mrs. Austin, the well-known authoress.

4. Much opportunity was afforded me of acknowledging the importance of the region of the feelings and the energy of the will when measuring the middle and posterior cranium.

In men of vulgar nature, or of scanty development, I found the middle cranium measuring below, or little above, 5". I took the measure of two thieves, both old criminals, and found that the height of their middle cranium amounted only to 4" 10" and 5" 1", and the width was 5" 2" and 5" 3".

In examining the skulls of many individuals of the wild tribes, as, for instance, of the Botocudans, New Hollanders, Guarapuans, Aleutians, Negros, Bashkirmen, I also found the middle cranium to be only of a height of 4" 8" to 5" 1", with the exception of the Bashkirmen, where I found 5" 5". But with poets, artists, and learned men, in civilized life, the average shewed a height of 5" 4" to 5" 7", and a width of 5" 5" to 5" 9".

875.—xxxiv.

With regard to the occiput, I found that its height stands in some relation to the energy of reaction; and this energy, whether it was of a more psychical character, or more connected with muscular strength, depended entirely on the greater or less degree of development in the region of intellect. So, for instance, the Arabian springers, who passed through Europe some time ago, were distinguished for an enormous height of occipital vertebra (the measure, beginning from the ear, amounted from 4" 5" to 4" 7" and even to 4" 8"), while we find quite a different size in persons who with a powerful will combine high intellectual faculties: there it was only 3" 7" or 4" to 4" 5"; in Ole Bull 3" 11", in Thorwaldsen 4" 3".

5. The measures taken of the middle vertebra of females differed from that of men in a much less degree than did the anterior and posterior vertebrae of their heads, but they varied much from one another respecting the middle vertebra, in accordance with the sphere of feelings, which was now more, now less predominant.

Very remarkable, in this respect, was the result which I obtained by comparing the heads of two great actresses, a mother and her daughter. The former, who is possessed of great dramatic talents, but of a steady and very reflecting mind, shewed a middle cranium only 4" 10" high, and 5" 1", and an occiput 4" 4" high; while her daughter, who is also a great vocalist, and combines with that talent great productive power of imagination as a performer, shewed a middle cranium of 5" height and 5" 6" width, and an occiput of only 3" 11" high.

A couple of common female prisoners, one guilty of poisoning, the other of child-murder, had only about 4" 5" and 4" 10" height by 5" 3" width.

The height of the occiput amounted, in females, usually but to 4"; and of all the measured heads none exceeded 4" 4"; while we have ascertained that in men it reaches 4" 8", which circumstance is in perfect accordance with the well known inferior energy of the other sex.

6. Relative to the different indication that we can gather from the height and width of the cranial vertebra, my observations have been in accordance with the above statements. Of striking

3 C

character in this respect were Goethe and Schiller. The latter, famous for his great tendency towards ideal philosophy, had a front of great width; while Goethe, whose intellect was as eminent in acute conception and observation of objects as rich in productive power, had a front of great convexity, but less width.

Similar instances, of an opposite character, can be abundantly found: Rauch, the excellent sculptor, shewed an anterior cranium 5" 4" high, but only 4" 7" wide; while Purkinje, a man of an acute reflecting mind, had only 5" height, but 4" 9" width.

A distinct parallel appears, in like manner, to exist between the difference in height and width of the middle cranium and the different dispositions in the sphere of feelings, the latter being either of a more subjective or objective nature.

Inconsiderable height, combining with great width, indicates a character decidedly and thoroughly influenced by external circumstances (thus in the skull of the above mentioned criminal, accused of poisoning, the width, 5" 3", surpassed the height, which was 4" 5"). The reverse indicates a character which is ruled by its own subjective feelings (the head, for instance, of a woman who, from fanaticism, became the victim to a serious derangement of the mind, shewed a height of 5" 5", which was surpassed only in a trifle by the width, the latter having been 5" 8").

In the occipital vertebra the height appears to have a relation to muscular power, while its width refers more to the motives and sexual energy of the individuals. A proof of what has just been stated is given to us even in ancient times, where the artists, hardly conscious of it, have represented this energy in the sign of a bull's neck, as we see, for instance, in the statue of Hercules and the fine specimens of the fauns. The same has been confirmed by many measures which I myself have taken from different individuals.

7. Finally, by comparing the width of the auricular vertebra with that of the orbits, I have constantly found a criterion which has enabled me to distinguish clearly between an individuality influenced more by his organ of sight, and another who is influenced more by his acoustic faculty. It affords a wide field for reflection that in the

head of Talleyrand, who said that "speech is given to man to conceal his thoughts," the width of the auricular vertebra surpassed that of the orbital region by 18", and in that of Ole Bull by 17"; while in Thorwaldsen the width of the auricular vertebra surpassed that of the orbits only by 13"; in that of Napoleon and the landscape painter, Dahl, by only 12 .

Upon thus arriving at the end of my communication, I beg to express a wish that they may attain the aim for which they are intended, namely, to instigate professional men to a deliberate study of craniology, to induce artists and well-educated persons in general to direct their observation to the enormous variety of forms in the human head, and to derive, by comparing the corresponding faculties of the psyche, some important and interesting results which will bear upon the study of anthropology; and finally, I have attempted to establish amongst the public at large a due degree of respect for, and acknowledgment of, the importance of craniology, a study which, when truly based, deserves, like every other science, to be ranked amongst the ever valuable and spiritual heirdoms bestowed upon mankind.

10, Carthusian Street, Charterhouse Square,

USE OF THE TROCHLEA OR PULLEY, GENERALLY, IN THE ANIMAL ECONOMY.

To the Editor of the Medical Gazette.

SIR,

As an appendix to the communication which lately appeared in your pages on the use of the trochlea, permit me to add the following observations. Formerly, I was accustomed to regard this as an apparatus in the animal economy *sui generis*; overlooking other contrivances whose use seems analogous, if the opinion I have advanced be correct. It may, perhaps, not be deemed impertinent to remark, that the various degrees of adhesion (or obstacle to motion of bodies at rest, in contradistinction to friction) depends upon the breadth, the form, and the elasticity of tangent surfaces. Thus, there would be no adhesion in a material globe and tangent plane, if both were perfectly hard. A considerable adhesion, however, is produced

by the wheels of a railway engine, by reason of the want of absolute hardness, still more by the break, because the tangent surfaces are larger, and most of all when a cord or band is wound many times round a fixed beam or cylinder, by which the smallest force would be made to counteract the greatest force, as a man at one end of a cable wound round a ship's windlass keeps the largest anchor suspended at the other. To fix the arm in order to some nice manipulation, as in removing a cataract, we rest our elbow on the hip, and the little finger on the patient's temple for a *point d'appui*. But, whatever steadiness the hand has, independent of these auxiliaries, as also the stability of the foot, is owing, in the writer's judgment, to the contact of tendons with certain ligaments, on the principle of the break.

Thus it would appear that the office of such ligaments as the *lig. carpi commune dorsale*, the *lig. carpi volaria proprium et commune*, together with the *lig. cruciatum*, is not merely to confine the tendons in order to beauty and compactness, but that it is also to compensate the difference of countervailing forces. For the foot represents a lever of the second kind, viz. that in which the weight is placed between the power and the fulcrum. If we raise ourselves on tip-toe, the toe becomes the fulcrum, and the flexor muscles (the *gastrocnemii* and *soleus*) the moving powers; whilst by standing on the heel the order is reversed, this being the fulcrum, and the extensor muscles the moving power. But when these contending powers are both exercised together, as in standing, the crucial ligament, like the *trochlea*, when the eye is at rest, takes on its passive function. Here, however, the analogy ceases, since the antagonist muscles of the extremities, whatever be those of the eye, are voluntary. I propose returning to the subject ere long, unless, indeed, my position should in the meantime be refuted, or prove to have been already anticipated by others. It is hard now-a-days to discover any thing new under the sun, and therefore with becoming diffidence, I subscribe myself, Mr. Editor,

Your obedient servant,
ZETA.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

A Manual of Medical Jurisprudence.

By ALFRED S. TAYLOR, Lecturer on Medical Jurisprudence and Chemistry in Guy's Hospital. Post 8vo. pp. xiv. & 679. London, 1844. Churchill.

We venture to say, that there was but one feeling on the part of the profession connected with the "*Elements of Medical Jurisprudence*," by Mr. Taylor, of which the first volume appeared so long ago as 1836; this feeling was regret that the work was not completed. The promise was so full, the ability displayed so unquestionable, that all who felt jealous of the honour of our national medical literature hailed with delight the appearance of a comprehensive and original work of English growth, on one of the most important and difficult departments of our science. The work, however, went no farther than the first volume. The scale upon which it was commenced, and the form of publication together, would have rendered it impossible to complete the work in less than four goodly octavo volumes; and as these are not the days which insure success for books on science in any save the most economical forms, probably both Mr. Taylor and his publisher took alarm. We should have been pleased, then, each year that has passed since 1836, to have seen Mr. Taylor proceeding with his labour; we should have had means of better information than we possessed till very lately within our reach, and so we should have been more *au fait* in matters of state medicine than we were. But the delay that has occurred has doubtless worked for good: our author is some years older than he was in 1836; he has pursued his subject with unabated zeal during all this time, and instead of having the tree, however richly laden with blossom, to admire, we have now the bough bending under ripe fruit, which we gather with assurance not only of its safety but of its wholesomeness. And then, instead of four octavo volumes, we have the results of Mr. Taylor's accumulated experience in a single volume, of the most elegant typography and paper that can be conceived—a

book for the drawing-room table rather than the student's dusky shelf.

By *medical jurisprudence*, says Mr. Taylor, we are to understand that science which teaches the application of every branch of medical knowledge to the purposes of the law, and he vindicates its claims on the attention of the profession on two grounds: 1st, because the subjects of which it treats are of practical importance to society; and 2d, because they are not included in the other branches of a medical education. He who pays any attention to the accidents that are every day occurring in connection with coroners' inquests, criminal trials, and commissions de lunatico inquirendo, must, we should think, have his eyes widely opened to the vast importance to the community of this medical jurisprudence, which is a kind of crown or blossom of the entire of the medical sciences, in their relations to society, just as physic, and surgery, and midwifery, are their crown or blossom in reference to the individual.

How nobly did our profession show in the late most interesting trial of Belany for the murder of his wife, some comment upon which we made in our last week's *GAZETTE*. But this is only the last instance in which our services to the community were brought into a somewhat prominent position. And as we have happened to touch upon this point, we think that we cannot do Mr. Taylor greater justice, nor our readers a greater favour, than by extracting the principal part of his chapter on "Poisoning by hydrocyanic or prussic acid."

"Poisoning by prussic acid," he says, page 250, "is commonly the result of suicide or accident; it cannot be easily administered with a murderous intent, except where it may be substituted for medicine." This is rather a curious coincidence with the direction which our suspicions took in connection with Belany—we all thought he had given the dose with the tea-spoonful of Epsom salts. Wherefore "it cannot easily be administered with a murderous intention," we own we do not see quite clearly. Mr. Taylor then goes on to describe the symptoms produced by prussic acid.

"*Symptoms*.—The time at which these commence in the human subject has not been accurately ascertained,

because the case is seldom seen until the patient is dead. When a large dose has been taken, as from half an ounce to an ounce of the diluted acid,—the symptoms may commence in the act of swallowing, or within a few seconds. In no case, probably, is their appearance delayed beyond one or two minutes. When the patient has been seen at this period, he has been perfectly insensible: there was convulsive respiration at long intervals, and the patient appeared dead in the intermediate time.

"The following case, communicated to me by my friend Mr. French, occurred in June 1837:—it presents a fair example of the effects of this poison in a fatal dose. A surgeon in large practice swallowed seven drachms of the common prussic acid. He survived about four or five minutes, but was quite insensible when discovered, i. e. about two minutes after he had taken the dose. He was found lying on the floor, senseless,—there were no convulsions of the limbs or trunk, but a faint flickering motion was observed about the muscles of the lips. The process of respiration seemed to cease for some seconds:—it was then performed in fits, and the act of expiration was remarkably deep, and lasted for a long time. The deceased swallowed the poison while ascending the stairs; his body was found on the landing. The bottle had rolled some distance from him, and the stopper was lying in another direction.

"Simon mentions a case in which an ounce was taken, and the symptoms were precisely similar. There was besides coldness of the hands and feet; but no pulse was to be felt. In all such cases, the breath exhales a strong odour of the acid. Convulsions of the limbs and trunk are sometimes met with among the symptoms. The finger nails have been found of a livid colour, and the hands firmly clenched."

He then goes on to speak of the post-mortem appearances, which he describes as slight and insignificant.

"On opening the stomach, the odour of prussic acid is commonly very perceptible for several days after death. If death has been rapid, and the inspection recent, all the cavities, as well as the blood, have the odour: but the organs of persons who have died from natural causes have been occasionally

found to present a similar odour. I once perceived it in the brain of a subject who had died from ordinary disease, and whose body was examined soon after death. Again, it is not always present in poisoning by prussic acid. The odour was not perceptible in the body of a youth who had been killed by three and a half drachms of the acid, and whose body was inspected thirty hours after death. In a case reported by Dr. Geoghegan, where a man swallowed an ounce of prussic acid, and was found dead, the only morbid appearance of note discovered, was a patch of dark red extravasation under the mucous membrane of the stomach, near the pylorus. The stomach, in this case, exhaled the odour of hydrocyanic acid, although it had been exposed for three days, but the poison was then easily detected by the usual means in its contents. From this account it will be perceived, that there is nothing to be derived from an inspection of the body at all characteristic of the mode of death; and probably no suspicion would be excited, except for the presence of the well-known odour.

*"Quantity required to destroy life.—*This is a very important question: and it is made somewhat perplexing by the fact, that, beyond a certain dose, the weak and the strong acid appear to act with equal rapidity (Christison, 658). It has been already stated (antè, p. 70), that six drops have been found to destroy the life of an animal—as rapidly as one ounce of the same acid—the animals being alike in strength and vigour. If any inference could be drawn from these experiments applicable to the human subject, it is clear that the view often adopted, of the rapidity of death being in proportion to the largeness of the dose, is erroneous. This view may be true to a limited extent; but it appears to me that a most improper application of the doctrine has been made from a few experiments. Admitting that two drachms of Scheele's acid will certainly kill an adult within a given period, it by no means follows that four times that quantity would kill a similarly constituted person within one-fourth of that period. Yet this has been made the basis of evidence by medical witnesses, as if it were a positively established fact. I have sought through works on toxicology, and our periodical journals, in vain, for facts by

which such a view could be supported. It is directly opposed to what we observe in the action of other poisons; for it is in general impossible to say within what time a case will prove fatal, from the actual quantity of poison taken. In a case related by Dr. Geoghegan, a quantity of the acid, equal to almost twenty-eight drops of the English pharmacopœial strength (at two per cent.), was taken by a gentleman without any effect, the dose having been gradually raised to this point, but no bad consequences whatever had resulted from the quantity previously taken; he now raised the dose to thirty-seven drops, and in two minutes he was seized with the usual symptoms, and nearly lost his life (Dublin Med. Journ. viii. 308). The quantity of strong prussic acid swallowed in this dose was less than three quarters of a grain, which is the largest quantity I have known to be taken without destroying life. This case shews that there is a very narrow line between the quantity of the poison which may be taken with impunity, and that required to produce death. In determining the quantity necessary to prove fatal, we must, it appears to me, avoid the results obtained by experiments on animals, and look to those facts only which have been ascertained from observation on the human subject. In general, the quantity taken is extremely large; but the smallest dose which is reported to have caused death was in the case of seven patients in one of the hospitals of Paris. By mistake, a dose equal to 0.7 grain of real acid was given to each patient, and they all died in from thirty minutes to three quarters of an hour. The symptoms began in ten minutes, and there were in all, at first convulsions and then coma. This quantity would be equivalent to about thirty-five drops of the pharmacopœial acid, and to fourteen drops of Scheele's. It has just been stated, that Dr. Geoghegan's patient, who took a similar dose, recovered. A case is related by Sobernheim of a physician at Rennes, who swallowed a teaspoonful of Scheele's acid, and some hours afterwards, another teaspoonful of Vauquelin's acid. The two doses were equal to about one drachm and a half of Scheele's acid. In a few minutes he fell senseless, and was seized with convulsions and tetanic spasms. He recovered his senses, and was able

to prescribe for himself in about three hours, but he did not wholly recover for thirteen days. Admitting that the strength of the acid was as represented, this is the largest dose which has been taken without causing death; but knowing what uncertainty there is on this point, and that, in the Parisian cases, seven persons were killed by doses equivalent to only one-third of this quantity,—I am inclined to think, that the acid, which had been prepared by himself, could not have been so strong as it was suspected to be. In answer to a question of this kind, it appears to me we should be justified in saying, that a dose of Scheele's acid above twenty drops, or an equivalent portion of any other acid, would commonly suffice to destroy life.

*"Period at which death takes place.—*Some remarks have already been made on this subject, and it has been particularly stated that beyond a certain point, we are not entitled to infer, that the rapidity of death bears any proportion to the quantity of poison taken. Experiments on animals might be adduced to prove either the negative or the affirmative of this proposition: a fact which clearly shows that they cannot be admitted, in this particular, as a basis for medical evidence. In the Parisian cases, where the same dose was given, death took place at very different periods—some died in a few minutes, and others only after three quarters of an hour. In one instance, in which seven drachms were taken, death took place within five minutes; in another, in which an ounce was taken, the individual survived in about ten minutes (Sobernheim). When the dose is two drachms and upwards, we may take the average period for death at from two to five minutes. It is only where the dose is just a fatal proportion that we find the individual to survive from half an hour to an hour. In this respect, prussic acid is like lightning—the person either dies speedily, or recovers altogether.

"But although death does not commonly ensue until after the lapse of a few minutes, insensibility, and consequently a want of power to perform acts of volition and locomotion, may come on in a few seconds. The time at which this loss of power is supposed to take place has already become an important medico-legal question, and on the answer to it, the hypothesis of suicide

or murder in a particular case, must rest. Dr. Lonsdale says on this point, that a drachm of Scheele's acid would affect an ordinary adult within the minute; and if the dose were three or four drachms, it would exert its influence within ten or fifteen seconds. When the acid is stronger, and the quantity larger, we are pretty certain of its *immediate* action, and the consequent annihilation of the sensorial functions (Ed. Med. and Surg. Journ. li.50). This opinion is founded entirely on experiments on animals. Dr. Christison ascertained that a quantity of poison, equivalent to two scruples of medicinal acid, did not begin to act on a rabbit for twenty seconds, and certainly, for so small an animal, two scruples are as large a dose as *five drachms* given to a grown-up girl. These statements appear to me to show that experiments on animals cannot enable us to solve this question: we should rather trust to the few observations made on the human subject, as well as to analogy from other sources,—as, for example, to the fact of survivorship after the receipt of what are commonly regarded as instantaneously mortal wounds. A case is related by Sobernheim, quoted by Dr. Gierl, where an apothecary's assistant went to a cellar in order to procure a drug. After a few minutes he was heard to cry out, 'hartshorn.' Some persons hastened to the cellar, and found him on the lower steps, just uttering the words 'prussic acid,'—he then fell dead, about five minutes after going to the cellar: it appears that he had tried to remove the cover from the bottle of ammonia, but had not succeeded. The quantity of poison which he swallowed is not stated.

"A case was communicated to me, some time since, by one of my pupils, where a man was found dead on the seat of a water-closet: he had died from prussic acid, and the bottle which contained the poison was found in his pocket, corked. These facts appear to show, that while, as a general rule, insensibility must supervene from a large dose of this poison in a few seconds, the individual occasionally retains a power of performing certain acts, indicative of volition and locomotion. This question was brought to a close issue in a case tried at the Leicester Spring assizes in 1829.

"A young man, named Freeman,

was charged with the murder of a female named Buswell, by administering to her prussic acid. A full report of this case will be found in the *MEDICAL GAZETTE* (Vol. viii. p. 759). The deceased was a maid-servant in the family of a chemist to whom the prisoner acted as an assistant. The deceased was one morning found dead in her bed: her death was evidently caused by prussic acid, and it was presumed that she had taken four and a half drachms of the poison; the bottle out of which she must have drunk it, or had it administered to her, holding an ounce, and still containing, when found, three and a half drachms.

"Owing to the position, and other circumstances connected with the body when discovered, it was inferred that she could not have taken the poison herself. Her body was lying at length on the bed, the head being a little on one side. The bed-clothes were pulled up straight and smooth, and they came up to the breast of the deceased; her arms were under the clothes, and crossed over the chest. On turning the clothes aside, the phial which contained the poison was found lying on her right side. It was corked, and there was a piece of white paper round it: the leather and string, which appeared to go round the neck of the bottle, were found in the chamber vessel. The medical question was, — Could this quantity of poison have been taken, and the deceased have afterwards performed these acts herself? Five medical witnesses were examined, and the opinions of four of these were strongly against the possibility of the acts having been performed by the deceased. One of these ascertained that a dog, to which the same quantity of acid was given as was taken by the deceased, died in about three seconds. The medical opinion was founded on experiments of this kind, for there were no cases from the human subject by which it could be supported. All the acts to which the opinion referred might be performed in from five to eight seconds, and there is nothing to warrant us in supposing, that under the above-named dose all power would necessarily have ceased before that period had elapsed. Dr. Christison's experiment on the rabbit would lead to the inference, that even five drachms would not begin to act upon a grown-up girl for twenty

seconds (668); and the results obtained by the witnesses from their experiments on dogs were by no means uniform, even allowing that they were justified in applying them to so important a question as this. The medical opinion was completely set aside by circumstances, and the prisoner was acquitted.

"A similar case has since occurred in Germany, and is quoted by Sobernheim. A young man swallowed four ounces of an acid (of four per cent.) equivalent to eight ounces of the pharmacopoeial strength. He was found dead in bed,—the clothes drawn up to his breast, the right arm stretched out straight beneath the clothes, the left bent at the elbow-joint, and on each side of the bed lay an empty two-ounce phial. There was no doubt of this having been an act of suicide. In deciding a question of this kind, it ought to be remembered, that very few cases have occurred where the poison was swallowed in the presence of a person competent to watch and form an opinion on so important a point; and no experiments on animals can justify us in saying whether insensibility, from a particular dose taken by a human being, began in five, eight, fifteen, or twenty seconds. In the German case, more than three times as much acid was taken as in that of Buswell, but even here there was time for the performance of very similar acts. It is besides much more difficult to understand how the poison should have been taken out of two phials, than out of one.

"Can a man, after having taken prussic acid, live sufficiently long to attempt or perpetrate suicide in any other way? The following case occurred in London in April 1839:—A solicitor's clerk was found hanging quite dead at his chambers. He had evidently taken prussic acid, for a cup was lying near him which had contained that poison. The medical witness here very properly inferred, that the man did not swallow the poison until after he had adjusted the rope round his neck. It could hardly be admitted that a man should have power to hang himself after having taken a large dose of this poison, but a person might be found drowned with prussic acid in his stomach, and without this fact being incompatible with suicide. It is, however, a matter of doubt, determinable only by special circumstances, whether a man could

destroy himself by fire-arms after having swallowed the poison.

"This question often presents itself in another form, namely, whether the act of poisoning was the result of accident or suicide,—a most important question, where the life of the deceased is insured. In general, the circumstances are such as at once to explain the nature of the act; but a medical witness must remember that there is no case in which suicide may be so secretly perpetrated by poison as by means of prussic acid. There are, besides, many ways in which the means of death might be concealed; and as it is so little the custom to cause an inspection to be made of the bodies of those who have died suddenly, unless a suspicion already exists of death having been caused by poison, such cases might easily escape detection. In the event of litigation ensuing, in respect to a policy of insurance, it may be too late to discover any traces of poison in the body. It is proper, therefore, to remark, that the effects of prussic acid may be easily confounded with all diseases which are liable to destroy life suddenly, such as epilepsy, apoplexy, and diseases of the heart.

"The case of Mrs. Nuclean, who was found dead in her house at Cape Coast Castle, in October 1838, is interesting to the medical jurist, in relation to the question of suicide or accident. Her attendant, in going to the room of the deceased, found some difficulty in opening the door, in consequence, as it appeared, of the body having fallen against it. The deceased was lying on the floor quite senseless, with an empty bottle in her hand, uncorked, and labelled 'hydrocyanic acid, medium dose five minims.' There was a feeble pulsation of the heart, which soon ceased. It appeared that the deceased was in the habit of taking prussic acid as a medicine, and the medical witness supposed that she might have taken an overdose, and have thus been killed accidentally; he was so fully convinced that the medicine was the cause of death, that he did not open the body. By this omission the case was left in mystery; for had the body been inspected, and the larger portion of the contents of the bottle been found in the stomach, there would have been no doubt of its having been an act of suicide, since a well-informed person

like the deceased was not likely to have swallowed by accident a large dose of poison, with the deadly properties of which she must have been perfectly acquainted. If the acid were taken medicinally, and an overdose swallowed by accident, it is singular that the bottle should have been found in her hand; since we cannot suppose that any well-informed person would take prussic acid medicinally, by swallowing it from the bottle itself. In consequence of the omission to inspect the body, it is difficult to say whether this was an act of suicide or the result of accident.

"*Treatment.*—There is no known antidote to this medicine. Experience justifies us in employing stimulants, such as diluted ammonia, to the nostrils, and frictions of the compound camphor liniment to the chest. Chlorine has been strongly recommended to be injected in the state of solution into the stomach; but admitting that it were at hand to be administered in a case of poisoning which seldom lasts above a few minutes, it is a remedy of very doubtful character. It has been proposed to apply electricity in the course of the spinal marrow; but the best remedy, and that which is always applicable, is cold affusion. In experiments on animals this has been found an efficacious mode of treatment, and also in one case in the human subject which is reported by Dr. Banks of Louth. A girl took by mistake in medicine, thirty drops of prussic acid. Immediately afterwards, she sprang up convulsively from her seat, and became senseless. Her teeth were firmly set, and her eyes staring and fixed. Stimulants failed to rouse her:—the limbs became flaccid;—the pupils dilated, and she was wholly insensible;—the respiration was slow, and the pulse scarcely perceptible. A stream of cold water from a pitcher was allowed to fall from some height on the region of the spine. In a minute she began to move, and became convulsed; her symptoms abated, and in a few hours she was quite collected. She recovered in a few days, but there is hardly a doubt that she would have died, had she not been thus treated."

We have selected this chapter on prussic acid both because from recent circumstances we believe it will be felt as interesting, and because even since it was written and sent forth to the world

an antidote for prussic acid has been found. "If," say Messrs. T. and R. Smith of Edinburgh, in a note to a friend, which we have had an opportunity of perusing, "a quantity of a mixed salt of the protosulphate and persulphate of iron be added along with an alkaline carbonate to a solution containing prussic acid, all trace of the acid immediately disappears." Thus doth science advance in her path to enlighten and to save; so do mankind become debtors to those who consecrate their lives to her service!

The interesting summary quoted will give our readers a fair, and no more than a fair, idea of the comprehensive and clear way in which our author treats one of his subjects. Every where, indeed, we find evidences of extensive reading and laborious research; the copious literature both of France and Germany on the subject of Medical Jurisprudence is laid under frequent contribution, and we have the pleasure of meeting with the accumulated stores of science and experience on this branch of knowledge, it may be said of the whole world, condensed and made accessible in this admirable volume. It is, in fact, not only the fullest and most satisfactory book we have ever consulted on the subject of which it treats, but it is also one of the most masterly books we have ever perused. So much precise individual knowledge, under the guidance of judgment and critical powers of so high an order as meet us in every page of Mr. Taylor's work, we have rarely encountered.

MEDICAL GAZETTE.

Friday, Sept. 6, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modò veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE MEDICAL PROFESSION BILL

—No. IV.

THE REGISTRATION CLAUSE—THE FINE UPON EFFICIENCY—PROPOSAL TO LEVY £75,000 FROM THE MEDICAL PRACTITIONERS OF GREAT BRITAIN AND IRELAND.

We did not at first see the new Medical Bill in the very objectionable light in

which it now meets us. We were probably flattered at seeing ourselves made the subjects of special legislative enactment; and the prospect of having the study and economy of the whole medical profession regulated by one comprehensive measure, dazzled our sense. We do not look a gift-horse in the mouth in presence of the donor; but when we have him in the stable, the curiosity we inherit from our mother Eve very certainly leads us not only to look into his mouth, but to examine him point by point; upon which, and having tried how he carries us, we first discover the true worth of the present. So has it been with this Medical Bill. We were every way inclined to entertain it handsomely, to welcome it cordially, and to find its enactments in harmony, so far as this was possible, with the state of things to which we had been accustomed, and pregnant with gradual and progressive professional improvement for the future.

We bitterly regret that we do not find it so. After having thrown open the honourable profession of medicine to all and sundry, tag-rag and bob-tail, and delivered over the ignorant public bound hand and foot to empiricism and incompetence, for no better reason as it seems—

"Than that the pleasure is as great,
Of being cheated as to cheat;"

—after having constituted a Council of Health and Education out of impossible elements, our Bill proceeds to enact:—"That a register shall be kept and published from time to time, under the direction of the said Council, of all persons who shall have been examined, and shall have received, and shall exhibit before the said Council, letters testimonial, as hereinafter mentioned, of their qualification to practise as a physician, or as a surgeon, or as a licentiate in medicine and surgery; for

which registry the Council shall be entitled to have from the person requiring to be registered a fee of *five pounds* in the case of a physician or surgeon, and a fee of *two pounds* in the case of a licentiate, which fees shall be applied toward defraying the expenses of this Act; and every person whose name shall be so registered, who shall be desirous that his name shall be continued in the published register, shall in the month of *January* in every year send to the said Council his name and place of abode, with the date of his testimonials; and the Council shall verify the returns so made to them by comparison with the register kept by them, and shall forthwith cause the names of all persons duly registered and so returned to them to be published in alphabetical order in their several classes, with their several places of abode, and dates of their testimonials."

Now it may be a good thing to make and publish a register of the regularly-educated men, physicians, surgeons, and licentiates in medicine, but it is nothing new, and we cannot see the propriety of their being made to pay for it. The thing is already now done by the College or Society to which we severally belong, free of charge to us individually. Having already paid handsomely for our diploma, license, or certificate, as the case may be, we peremptorily object to this proposition to pay any more.

The pretext for the registration fee of £5 and £2 is, that the expenses of the act may be thereby defrayed. Now we believe that a private act of parliament, which is unopposed, may be had for about £500; and here, of course, every body is feed for his trouble of preparing and carrying it through, from the clerk who draws it up in form, to the Right Honourable Member, it has been said, who takes charge of it in its progress through the House. But

a public act is prepared at the expense of the country; and the medical profession ought no more to be required to contribute to the expense of any act having reference to its members, than the honest trader should be required to pay the expenses of the act that is to protect him against the contraband dealer. With what shadow of justice, above all, could the fair trader be required to pay for an act that was to leave him subject to all his old liabilities and burthens, and to put the contrabandist upon a footing of perfect equality with him? And yet is not our new Medical Bill a proposition of this very kind?

The price of a private act of parliament, we have said, may be about £500; and we of the medical profession are required to pay for our Bill. Let us see what the sum may be which might be raised on the strength of the registration clause strictly enforced. We are in all, it is said, about 30,000 strong in the medical profession in these isles; of this number about 5000 may practise as physicians and pure surgeons, and 25,000 as general practitioners. At the rate of £5 per head from the doctors and surgeons, the sum that would be levied would obviously be £25,000; at the rate of £2 per head from the general practitioners, the sum raised would as obviously be £50,000. £25,000 + £50,000 = £75,000! verily a handsome sum to be taken from the pockets of a poor profession at one fell swoop! Sir James Graham must certainly have another motive for his bill than any that appears in its clauses: he cannot propose the levy of £75,000 as a means of covering an outlay of at most £500; he must be bent on making money of us,—of us whose lives are a ceaseless exercise of the charities that are dearest to man, and whose remuneration is either nothing, or entirely contingent on the power of the party who requires our aid to pay!

We will suggest another course to the Right Honourable Baronet, the Secretary for the Home Department, which he may discuss with the Chancellor of the Exchequer—it is the right one, we feel persuaded. What would he say to leaving us of the regularly educated profession out of the question entirely, and insisting on the very respectable gentlemen who carry on the practice of medicine without any education at all enrolling or registering themselves forthwith, and paying—what shall we say?—£5 per capitem for the privilege? This would be sense, this would be fair; we of the regular profession do not want to be enrolled. We are like the inhabitants of a generally respectable street, who do not place a man before each of their houses with a lantern to signify that it is a respectable house; but who set a man with a lantern before the single peccant domicile of the row, admonishing way-farers of the propriety of shunning bad houses: “good wine wants no bush;” and his fair fame, and his name on a brass plate to indicate his residence to whosoever seeks it, suffice the educated practitioner. Because I have vindicated my claim to consideration and to confidence, am I therefore to pay, *i. e.* to be subjected to a penalty? This appears to us a sad solecism; it is unquestionably a new feature in legislation at all events, and such a one as could only be vindicated by a desperate state of the public exchequer. I have hitherto done honourably and well; I have complied with all the requirements of the College or Company to which I belong; I have spent a large sum of money on my education, and given the prime of my life to the acquisition of professional knowledge; I have farther stood the test of competency, and obtained a testimonial to my trustworthiness, and therefore am I to be amerced to the extent of £5 or £2, according to my

position in my profession?—Not to the extent of fivepence, nor yet of twopence, Sir James Graham, if we should die for it, or, in peril of our lives from starvation, if we should be forced from our homes, to “distant barbarous climes, rivers unknown to song,” as the poet has it. These barbarous climes would at all events have their skies unclouded by Cæsars hanging blankets between us and the sun, these rivers would have their waters undisturbed by absurd legislation. Such will be the answer of the members of the medical profession to any so palpably unjust proposition. And here we leave our readers for the present.

MOVEMENT IN THE PROFESSION.

THE ferment does not subside. A good deal of scum shows itself on the surface, and doubtless a like proportion of dregs (though these do not appear) go to the bottom; but the liquor between the froth and the lees appears to acquire body, and generally shows itself bright and pure. We trust, as we have entered on this brewing figure, and are reminded thereby of our old friend Robert Burns, that a “loving cup” may yet crown recovered tranquillity among us. Burns says:—

“When neighbours anger at a plea,
And are as wud* as wud can be,
How easy can the *barley-bree*
Cement the quarrel!
Its aye the cheapest lawyer’s fee
To taste the barrel.”

We have a copy of proceedings at a meeting of the medical practitioners of the county of Surrey, held on the 22d August, at Epsom, for the purpose of taking into consideration the Bill for the better regulation of the medical profession; Mr. Martin, of Reigate, in the chair.

Resolutions were passed condemnatory of the proposed Council of Health

* *Wud*, mad.

and Education, of the proposal to remove all restrictions and penalties upon unlicensed practitioners of medicine, and of the Bill generally, as likely to be greatly prejudicial to the interests of the profession of medicine, and to the public welfare. Other resolutions were passed, approving of the manner in which the Court of Examiners of Apothecaries' Company had exercised their powers, and expressing an opinion that an act to amend that of 1815 might be so constructed as to meet every present difficulty, and attain all the objects sought for by the profession in general.

On Monday evening, the 2d inst. according to a notice which has been sent to us, the Committee of the East London Medical Association met for the purpose of considering the bill lately laid before Parliament by Sir James Graham, and passed resolutions expressive of unqualified disapprobation of the measure, "inasmuch as the Committee conceive that it must prove highly injurious to the public at large, and most ruinous to the profession. They consider the absence of all restrictions to the practice of medicine beyond the mere disqualification of holding public appointment deeply to be lamented, as it is evident that the mass of the population cannot possibly discriminate between the ignorant pretender and the regularly educated practitioner."

Another resolution was to the effect, that the cordial thanks of the profession and the community at large were eminently due to the Society of Apothecaries for their exertions to improve the education and raise the character of the general practitioner.

A third was a vote of thanks to ourselves for the manner in which we had exposed the inconsistencies of Sir James Graham's proposed measure.

On the 3d inst. a numerous meeting—the *Times* says there were 100 pre-

sent—members of the medical profession was held at Exeter Hall under the shield or on the summons of the Medical Protection Association, Mr. Asbury, of Enfield (!) in the chair. The purpose of this meeting was rather special or partizan than general—it was particularly to find fault with the Council of the Royal College of Surgeons for declining to receive a deputation from the association. Dr. Lynch was the leading speaker, and poor old Mr. Carpue, as a grand stalking-horse of all medical malcontents, was paraded as usual. Mr. Wakley was present, but seems only to have come forward upon somewhat urgent solicitation. He expressed himself as delighted with the spirit which had manifested itself in the profession; declared that the Council of the College of Surgeons had placed the great body of its members in the most degraded position before parliament and the country, and described the new charter as a bill of pains and penalties amongst members of the College at large. Finally, he exposed Sir James Graham as a grand medicine or mystery man, a brother of him of the Ioways, and like him prepared to practise and protect quackery.

A handbill, it seems, was circulated pretty freely to the parties who attended the meeting. We of the *MEDICAL GAZETTE* are not in the secret of these things, and cannot make any comment on its contents.

COLLEGE OF CHEMISTRY.

WE observe with much satisfaction, from a prospectus which has just reached us, that it is the intention of certain Noblemen, whose names are usually most prominent in all attempts to advance agriculture, to establish a College or High-school of Chemistry, associated with a laboratory for original research, after the manner of the Giessen school. A similar design was long ago entertained by Sir Humphry Davy, but was frustrated by his pre-

mature decease. In the present state of chemistry on the continent we have a demonstrative proof of the great results which would inevitably have flowed from it had it been carried into effect twenty years ago. Our own backwardness at the present moment renders it high time that some efforts should be made to place this science upon a better footing, to give it an impulse and a direction corresponding in some measure to the vigorous advances it is making in France and Germany. We sincerely hope that since the higher patrons of science are ready to bestow their time and their money upon an undertaking of this kind, they will not lack the co-operation of the medical profession; to every member of which, chemistry in its application to physiology and pathology is of paramount importance, and scarcely less so to the improvement and extension of the *materia-medica*. The plan we perceive embraces the formation of local committees in country towns and districts, and we should think that country practitioners could not dispose of their leisure better than by assisting to establish the College of Chemistry.

INCREASED MORTALITY

AMONG

CHILDREN UNDER THE HANDS OF UNEDUCATED PRACTITIONERS,

AND FROM WANT OF ALL MEDICAL
ATTENDANCE.

SOME short time ago, Mr. Chadwick did us the favour to send for our perusal what he believed to be an important communication from Mr. Leigh, surgeon, Manchester, upon the above subject, and suggested that Mr. Leigh should be written to, and his permission asked to publish his letter. This was done, and the following is Mr. Leigh's manly reply to our note:—

To the Editor of the Medical Gazette.

Dear Sir,—In reply to your note of Aug. 20th, I beg to place at your entire disposal the letter I addressed to Mr. Chadwick on the 3d May. Should you feel disposed to publish it in the *MEDICAL GAZETTE*, with or without any comments, I shall have not the slightest objection to your doing so; but, con-

ceiving the subject to be of great importance both to the public and the profession, I shall be happy to furnish you with any additional information in my power. I shall be glad to find that the subject is taken up by the profession in a proper spirit, and so forcibly brought before the legislature as will insure at once to the profession that protection which it has a right to demand on the score both of the cost and the education of its members; and to the public a safeguard against the wholesale destruction of life which results at present from fraudulent incompetence on the one hand, and gross ignorance of the necessary qualification of a medical practitioner on the other.

I happen to hold the office of Registrar of Births and Deaths in Manchester at present, and I believe that I do not exaggerate when I say that nearly one-third of all the deaths of children that I register appear to have been from remediable diseases, and that the deaths have occurred either under the necessarily improper treatment of uneducated persons, or, what is nearly as bad, from no treatment at all.

I am, dear sir,

Yours very truly,

JOHN LEIGH.

St. John's Street, Manchester,
Aug. 31, 1844.

The letter addressed to Mr. Chadwick is as follows:—

Sir,—I have taken the liberty of again addressing a few observations to you on the mortality of children, more particularly in connection with medical quackery. During the quarter ending March 31, 1843, I have been very particular in ascertaining with as much precision as possible, the causes of death in children. When they had regular medical attendance, I have sought the information from the attending surgeons, and in other cases by a careful inquiry into the history and symptoms of the diseases. I am, therefore, disposed to believe, that the causes of death have been registered in my district during the last quarter with more than usual accuracy, and rely therefore on the table I have formed with much confidence.

The total of births registered during the quarter is 311, and of deaths 245.

Of the latter, 134 were of children

under five years of age, and may thus be classed :—

Under 1 year old	56
More than 1 year old, and under 2 years	37
More than 2, and under 3 .	15
" " 3 " " 4 .	12
" " 4 " " 5 .	14
	<hr/>
	134

The causes of death may be thus classed :—

Measles	19
Scarlatina	11
Peripneumony . .	34
Croup	8
Hooping Cough . .	4
Convulsions . . .	18
Hydrocephalus . .	11
Marasmus	14
	<hr/>
	119

The rest being from irregular causes.

Of these 134 children I ascertained that 30 were attended by *retail druggists who had received no medical education*; whilst 4 had no advice or attendance of any description.

I think that I stated to you, some time ago, that I thought I had registered annually about 100 deaths of children who had had no proper medical attendance; I felt satisfied that this was below the truth, for this quarter would give an annual number of 156; and even this, great as it appears, I am as well satisfied is very greatly below the real number; for I have ascertained the facts only by an indirect system of questioning, being apprehensive that direct and pointed questions on the subject put to the informant might be deemed impertinent, and lessen the present good repute of registration. From the answers I have received I have been convinced on many occasions that the cases had been attended by druggists alone, though the informants would not confess it. These cases I have taken no notes of; the others, viz. the 34, I have positive information of.

I requested my friend Mr. Bennett, the registrar for Ancoats district, and the only other medical man who is a registrar in this, the Manchester, Union, to make a similar series of observations; he has done so, and found less difficulty

in arriving at the truth: he has obligingly furnished me with the results of his inquiries.

During the quarter ending March 31st, 1843, he registered the deaths of 212 children under 5 years of age. Of this number only 78 were attended by properly educated medical practitioners; and 134 were either attended by druggists or had no attendance of any description, being at the rate of 536 per annum in this district alone! This number is perfectly astounding, and calls for some immediate steps to abate so great an evil. For that an immense number of these little creatures were sacrificed to ignorance or negligence, there can be no doubt.

The poverty of the population in the Ancoats district, with the very limited number of medical practitioners in it, are to be ascribed as the chief causes, together with the facilities afforded in running to the nearest druggist's shop. But the druggists do more than merely prescribe medicines over the counter, they also visit and attend parties at their own homes. I myself was called a short time ago to visit a patient labouring under hydrothorax, which had come on from grossly improper treatment. She had been attended by a neighbouring druggist, who seeing his patient rapidly sinking, got frightened, and left the case. He then wanted to attend the case with me; but this I of course refused. The patient ultimately got well, but had she died the man ought to have been tried for manslaughter.

Mr. Bennett has classed his cases much in the same manner that I have done, and it will be seen that most of them are incidental to, and naturally resulting from, the winter season, viz., peripneumony or inflammation of the lungs, croup, the pulmonic affections supervening on measles and scarlatina, hydrocephalus, many of the cases acute, and hooping cough, amounting to 97 in my district the other 32 not affecting any particular season.

The mortality in my district this quarter, then, amounts to considerably more than two-fifths of the whole children born before they attain the age of five years, and this is below the average, for in some quarters the mortality of children has been more than one half of the children born. Now these dis-

cases that I have just specified, although when neglected almost certainly fatal, are when early attended to very much within the reach of medical treatment. Acute inflammatory diseases rapidly run their course in children, whose great excitability renders them very prone to take on this action; but medical men do know how to combat and subdue inflammation, and when called sufficiently early, they in most cases succeed. I have before me the reports of the dispensary for children of this town, situated just on the verge of my district.

In the report 1841-2, it appears that 1680 cases were admitted as patients and treated by the officers of the institution, and of this number 75 died: being at the rate of 4·4 per cent. only. This fact alone shows how remediable are most of the diseases of children. I regret that no classification of the diseases has been published by the officers of this institution; it would have possessed great interest in connection with this question.

I trust, sir, you will not deem this information unimportant; it has been forced on my mind in the ordinary exercise of my duties in the office I hold as registrar, and when it is considered that it is perhaps a more fruitful source of mortality than any other single cause whatever, you will allow that it calls for some special interference. More lives are annually sacrificed to ignorance and negligence than to any single cause whatsoever, whether of accident or disease. One half of all the children born in this part of the country are swept off before attaining the age of five years.

I have confined my observations to children solely, because in these the mortality is greatest, and the responsibility of those having the management of them also the greatest.

When disease occurs in adults they generally get for themselves better treatment than they obtain for their children. They have either a private medical attendant, or they are members of some club, or they avail themselves of the medical charities or the services of the Union surgeons; but their progeny, when disease overtakes them, are suffered to perish without assistance, or the useless or pernicious advice of some ignorant empiric hurries them on to the grave. The little sufferers cannot tell their ailments, and opiated cordials

are employed to still their cries and lull them into the sleep of death.

If any further remark or tables connected with these subjects will be acceptable to you, I will do my best to obtain them.—I am, sir,

Your obedient servant,

JOHN LEIGH.

6, St. John's Street, Manchester,
May 3, 1843.

[Such a document as this speaks volumes, and shows how short-sighted and ill-informed are those who would leave the ignorant public without protection. We have no access to great people; we are only known to our brethren as a zealous labourer in the professional vineyard—a stony and somewhat niggardly field it is—upholding the honour and vindicating the importance to the community of our noble calling; but we shall take care that it be their own fault if Sir James Graham and Mr. Macaulay are not made acquainted with the important letter of Mr. Leigh, for we have requested our publishers to forward a copy of this number of our publication to the residences of both of these gentlemen.—ED. GAZ.]

PRODUCTION OF FALSE MEMBRANES

FROM THE MUCOUS SURFACE OF THE
BLADDER UNDER THE INFLUENCE OF
CANTHARIDES APPLIED TO THE SKIN.

BY M. MOREL-LAVALLÉE.

ALL the world knows that considerable irritation of the urinary passages occasionally ensues upon the application of a blister, or from the internal exhibition of cantharides. M. Morel-Lavallée has quoted four cases in which this irritation went the length of producing false membranes, which were expelled in shreds from the urethra, and bore an exact resemblance to the false membranes that sometimes form on a blistered surface of the skin. In these cases there was a considerable quantity of albumen in the urine. The author had not himself had any opportunity of examining the state of the vesical mucous membrane during the production of false membranes; but he refers to a case, reported by M. Vidal de Cassis, of a female who had died of a pleurisy, for which repeated blistering had been employed in vain, in which the membrane in question was found "red and thickened, like the conjunctiva in purulent ophthalmia."—*Comptes Rendus, Juillet* 1, 1844.

NUMBERS OF THE MEDICAL PROFESSION IN GREAT BRITAIN.

FROM the answers and returns made pursuant to an Act, entitled, "An Act for taking an account of the population of Great Britain," just published, it appears that there are of

INOCULATION OF VERATRINE IN NEURALGIA.

M. LAFARGUE transmitted to the Academy an account of the good effects he had obtained in facial neuralgia from the inoculation of veratrine. The veratrine is mixed with a drop of water, so as to have a suitable consistence, and is then introduced exactly as in inoculation with the vaccine virus. Directly on the operation being performed, the patient experiences a pricking sensation in each puncture, similar to that caused by reiterated pricks of a needle; this sensation begins to lessen after the lapse of ten minutes, and disappears in about an hour. M. Lafargue repeats the operation night and morning, making about a dozen punctures at the point where the pain is most severe. In limited paralysis, especially of sensation, the same proceeding is very advantageous.—*Gazette Medicale.*

BOOKS RECEIVED FOR REVIEW.

The Dispensing Chemist's and Medical Pupil's Assistant; containing Latin Directions, with their Translations, for every species of Medical Prescription. By John F. Burke, Member of the Royal College of Surgeons.

Researches into the Physical History of Mankind. Vol. IV. By James Cowles Prichard, M.D. F.R.S. &c.

Hints to Mothers for the Management of Health during the Period of Pregnancy, and in the Lying-in Room. By Thomas Bull, M.D. &c. 4th Edition.

LECTURES
ON THE
NATURE AND TREATMENT OF
DEFORMITIES,
*Delivered at the Orthopædic Institution,
Bloomsbury Square.*

BY R. W. TAMPLIN, F.R.C.S.E.
Surgeon to the Institution.

—
ON TALIPES EQUINUS.

THE plan I propose to adopt in these lectures is this:—I shall first direct attention to the deformities of the feet; the treatment of these being the groundwork of the treatment of deformities in general—having been in fact the origin of the new method of treatment which has now extended itself to every variety of deformity of the body. After the deformities of the feet, I shall consider in their order those of the knee, hip, spine, neck, and upper extremity. I intend also to illustrate the several operations I discuss practically, when I am enabled to do so, at the termination of each lecture.

The most simple form of distortion is *talipes equinus* or *horse-foot*, so called from its anatomy corresponding to the natural anatomical formation of the foot of the horse. It consists in complete elevation of the heel, unaccompanied by lateral distortion; the concavity of the arch of the foot being increased; the toes *extended in position*, though occasionally *contracted in form*, in consequence of the extreme flexion to which they are subjected; and the metatarsal bones frequently diverging from each other (vide fig. 3), by which the anterior part of the foot acquires an appearance of increased width; which, indeed, it virtually possesses. The patient in walking rests entirely on the heads of the metatarsal bones; the os calcis is almost perpendicular, from the contraction of

the gastrocnemius; the astragalus lies obliquely in the articulation, presenting its heads forwards and downwards, and frequently projecting, in consequence of the separation of its superior surface from the scaphoid bone, and the elongation of the ligament that lies between them. The cuneiform and the metatarsal bones change their position, so as to correspond with the direction of the foot, whilst the phalanges are extended, and appear set on at right angles to the metatarsal bones: from the pressure occasioned by the weight of the body, the ligaments on the dorsum of the foot are slightly stretched, whilst those in the sole become more or less contracted, according to the age of the patient, and the duration of the deformity.

As a general rule, the muscles, with the exception of the gastrocnemius, are in a state of extension on the anterior surface, and of contraction on the posterior, although not permanently so. This description, in its full extent, applies only to a perfect case of *talipes equinus*, such as may be seen in Fig. 1; but the same features of course exist more or less in every modification of this species of deformity; their degree depending on the severity as well as on the variety of the case, from the simple contraction at right angles, to the utmost possible elevation of the os calcis.

I have never met with pure *talipes equinus congenital*. The causes of the non-congenital deformity are numerous. The irritation of teething, worms, any derangement of the nervous system, wounds in the calf, rheumatism, scrofulous disease in the ankle-joint, or in the substance or tendon of the gastrocnemius. Not unfrequently, however, this deformity arises spontaneously, the patient experiencing no pain or inconvenience beyond the inability to bend the foot or ankle-joint in the act of walking, and retaining at the same time power over all the muscles.

Fig. 1.

Talipes equinus, the consequence of scrofulous abscesses of the leg: *a* is a projection formed by the head of the astragalus separated from the os scaphoides.

Fig. 2.

The cast of the foot represented in Fig. 1, after treatment, shewing the removal of the contraction of the toes by the restoration of the foot to its natural state.

When talipes equinus arises from *dentition*, it is often combined with contraction, and partial paralysis, of the upper corresponding extremity; occasionally, however, it is unaccompanied by any other deviation. Frequently in such cases there will be found paralysis of the anterior tibial muscle, so that the contraction would appear in these instances to arise from the balance of power being destroyed, and the gastrocnemius being thereby allowed to contract upon itself. Frequently we find perfect paralysis to have been connected with a fit, or great cerebral disturbance, which subsiding gradually, or

more quickly, leaves the flexors of the foot paralyzed. I have had opportunities of witnessing this contraction from its very origin: I was consulted by the parents of a child, 18 months old, that had contracted a limp which occasioned it frequently to fall; upon directing the child to be led across the room, I observed that in the act of progression the right heel was elevated the moment the left foot was carried forwards beyond the perpendicular line of the body, and that the toes diverged from each other when pressed upon by the weight of the trunk. On carefully examining the foot, I found partial loss of power in the anterior tibial muscle, and incipient contraction of the gastrocnemius, so that although I could flex the foot by using considerable force, yet upon withdrawing my hand, it re-contracted immediately. Upon inquiry I found that the child was suffering from the irritation of teething, and also from the small thread-worm; the gums were freely lanced, scammony and calomel administered periodically, and the child improved in health. Still, however, the deformity remained: a tin splint was applied behind the leg and foot, and coming at right angles under the latter; embrocations were used, and flannel bandages were applied to the entire limb; but even these means failed in restoring the natural condition of the muscles, and the tendency to contraction still remained. I then ordered one of Scarpa's shoes, which was worn for six months with beneficial effect. The child was then sent to the sea-side, and for a time appeared perfectly well; but the same tendency to contraction recurring, I proposed division of the tendo-Achilles, and the operation was done; since which time the foot has remained perfectly in position, and the child possesses free voluntary motion. This case is important, inasmuch as it would appear, on consideration of the circumstances attending it, that the contraction, although so *slight*, was *permanent*; as we find that the increased length given by the operation has allowed the anterior tibial to exercise its full function, and there has been no disposition to any return of the affection.

The irritation following a *puncture*, or *other wound*, sometimes sets up diseased action in the muscle of the calf, or in the nerves supplying that muscle, which resolves itself into gradual contraction of the gastrocnemius, although unattended with paralysis of the flexors of the foot, or even by any loss of power, at least so far as can be discovered. This does not occur at the time of the infliction of the wound, or during the subsequent healing process, but after the patient has to all appearance recovered from the effects of the injury; his attention being drawn to the circumstance by his inability to flex the foot completely; and the infirmity,

if unattended to, gradually increases until the os calcis is elevated to its extreme point; the *inherent* motion of the ankle-joint remaining unimpaired.

Fig. 3.

Talipes equinus from paralysis during childhood (patient æt. 15): illustrating the great increase of the arch of the foot and divergence of the metatarsal bones.

Fig. 4.

The foot represented in Fig. 3, after treatment: shewing the restoration of the arch of the foot by the removal of the contraction of the gastrocnemius simply.

Rheumatism occasions this deformity, as well as numerous others; in fact, there is not a joint in the body which escapes the influence of this disease. When talipes equinus arises from a rheumatic affection, it generally commences either during, or immediately after, the active stage of the disease; and appears to arise from the contracted position which is occasioned by the painful state of the whole of the textures belonging to the joint and surrounding it, and which causes the muscles to be kept in constant exertion to prevent the slightest motion;

the extensors preponderating, gradually extend the foot, so that when the patient is allowed to walk, he finds his heel elevated from the ground, or else finds an inability to flex the foot. This is perhaps the most serious form that can be met with, inasmuch as the synovial membrane and ligaments of the joint become thickened, and offer an obstinate resistance to the restoration of the foot to its natural position after division of the tendon, and even the foot is brought into position, unless great perseverance be used, the motion of the joint will not be restored. We are thus led to suppose that there has been an adhesive thickening and alteration in the structure of the whole joint, and that the contraction exists not in the muscle, or its dependent nerves, but that it has arisen purely from the position adopted instinctively by the patient to relieve himself from pain during the attack. This position is generally one in which the more powerful muscles easily obtain an ascendancy over their weaker antagonists, and although the *instinctive shrinking* from pain is undoubtedly communicated to these muscles by the nerves which supply them, still the *actual contraction* must be produced by a constant effort of the will alone to keep the limb and joint motionless; and therefore it is evident that the deformity thus occasioned is perfectly unconnected with the nerves and their centres, and exists independently of them when the disease has subsided, and the tenderness of the joint has disappeared. After the restoration of the foot to its natural position, the patient acquires all the power of voluntary motion, and the cure thus becomes perfected. You will not, however, meet with any deformity which will give you more anxiety, or require greater care, than the last; because in the others which have been mentioned, the joint itself offers no resistance, and is not the original cause of the deformity, so that having divided the contracted muscle or muscles, the cause and effect being removed, you will find the foot readily resume its position. Not so with a *rheumatic* deformity.

The next cause I shall mention is that of *scrofulous disease or ulcers* about the calf, tendon, or joint, but more especially ulcers about the calf or tendon. I had a patient under my care who, at two years of age, was attacked with scrofulous inflammation of the leg and arm, which continued until the age of six, a period of four years; in the arm the joint became diseased, and the affection terminated in complete ankylosis of the elbow-joint at right angles. The patient, however, possesses a very useful limb, and is enabled to follow his avocations with comparative ease. In the leg the disease did not permanently affect the joint beyond the irritation consequent on its close vicinity, which irritation,

after the healing of the wound, subsided, leaving no trace behind it: the calf and tendon, however, were covered with cicatrices, which adhered both to the muscle above and to the tendon below, and which, being influenced by every action of the muscle and tendon, gradually (as cicatrization became perfected), and almost insensibly, drew up the heel until it reached its highest possible elevation—the foot forming a perfectly straight line with the leg without the slightest deviation on either side, the patient walking on the very centre of the heads of the metatarsal bones (vide fig. 1, in which this case is represented); and a more complete specimen of talipes equinus could not be met with. On examining the foot, it was found that by the use of great force the smallest possible amount of motion could be discovered, sufficient to lead to the hope rather than to the assurance that the joint itself was uninjured. I proposed the operation, at the same time stating my opinion that the future result might not be altogether favourable: the patient submitted. On passing the knife behind the tendon, which was done with some difficulty, I found that the tendon itself was completely imbedded in cicatrix, and that from the deeper seated fibres to the upper surface the whole formed one mass: on attempting to cut the tendon in the usual manner, not the slightest impression could be made, tendon and cicatrix together yielding like a piece of Indian-rubber; I was therefore compelled to cut into it by the smallest repeated cuts, and, after great difficulty, I separated the whole to the very cuticle (for the skin itself was in a state of adhesion). In three or four days extension by means of Stromeyer's foot-board was commenced, and gradually increased for six weeks, at the end of which time the foot was brought to a right angle with the leg (vide fig. 2, taken from the cast)—not, however, without much difficulty and attention, for although everything had been divided which admitted of division, yet the ends were still kept in contact by the remaining portion of the cicatrix, which was firmly attached to the deep fascia and muscles, and extended the whole length of the tendon. The patient has, however, no paralysis of the anterior tibial muscles, or extensors of the toes, and now possesses a limited degree of motion of the foot; there is no tendency to re-contraction, and the patient walks in a common boot without any support.

There is another and more serious form of disease arising from scrofulous affection of the joint itself, and which admits of no remedy after the subsidence of the diseased action, perfect ankylosis then resulting. But in this variety of the deformity the position of the foot may be restored by the

careful application of support (that is, by means of splints) during the diseased action, or before the adhesions have assumed their permanent osseous condition; though in these cases, of course, permanent voluntary motion of the joint is out of the question, for in whatever position the restorative process becomes matured, in that position must the foot remain. This modified system of cure, however, can apply only to young subjects, as disease affecting the bones and joints of adults very seldom admits of cure, except by means of the amputating-knife.

The last cause of this deformity which I have to allude to is at present entirely hidden from our sight, and leaves us to speculation or theory. Our knowledge of the functions of the nervous system is limited, and this state of our ignorance disqualifies us from giving any satisfactory explanation as well of those deformities which arise without apparent interruption to the general health, as of those formidable and fatal affections, tetanus and hydrophobia. On none of these affections has physiology or pathology yet thrown any light, although both have been the peculiar study of many able members of our profession. We cannot, therefore, reasonably hope, whilst the cause of the more palpable and striking, and serious nervous disorders, still remain involved in mystery, that the less remarkable and the milder derangements which sympathetically occasion paralytic deformities should be easily traced and comprehended. In the cases I now allude to, it will be found, on inquiry being made into the cause, that the parents or friends of the patient will reply, "that the child was put to bed in perfect health and slept well, but that upon taking it up in the morning it was found to have lost the use of one or both extremities; or that the leg was observed to be motionless; upon recovery from which state a weakness remained in the foot which terminated in the deformity." A case of this kind occurred in my practice three years ago, in which the heel was elevated about three inches from the ground, and in which perfect paralysis existed, and still exists, in the anterior tibial muscle, although the patient, during childhood, was not remembered to have suffered any illness. That some diseased action had gone on at one time unobserved cannot be doubted, nor can there be a question that this diseased action was connected with the brain or spinal chord; yet, strange to say, the mischief in this case proceeded to the serious extent mentioned above, and resulted in permanent paralysis without having affected the health of the child, who would unquestionably, by crying, or otherwise, have at once announced any pain or inconvenience that it might have felt. This is a circumstance occasioning much surprise and curiosity. We have

several cases of this kind on the books of the Charity, which all leave the occurrence of these sudden attacks of the nervous system a fact yet to be accounted for. There is another species of spontaneous contraction which I have met with in the adult, without, however, the addition of paralysis. The patient will tell you that he or she has had no illness, but that they found their heel or heels, for it sometimes occurs in both feet, gradually becoming elevated from the ground, causing severe pain in walking, and at length preventing them from pursuing their daily avocations. I saw a case of this kind, a short time since, in St. Bartholomew's Hospital, through the kindness of Mr. Lawrence, in which both feet were affected, the heels being drawn up to their full extent, or nearly so. The patient stated that the affection had come on gradually, and that he could assign no cause; there was no paralysis of the muscles in front of the leg, and after the feet were brought into position he could flex them and extend them at will. We have had two or three cases of the kind among the out-patients in which no trace of any cause could be imagined or discovered. The patients had been subjected to no illness, had felt no pain, had not been deprived in any way of the power of following their usual employments; there was no paralysis, nor, so far as could be discovered, any loss of power; and yet, by insensible degrees, the os calcis was drawn up—the first notice the patient received being a difficulty in walking, and an inability to bend his foot, terminating in complete elevation of the heel. What can be the morbid condition which induces such a malady? The probability is that the origin of it lies in the spinal chord, which exercises a sort of perpetual irritation throughout the whole muscular system. This is not a perpetually active irritation, but rather a universal pervading stimulus; the former would inevitably result in spasmodic contraction of the muscles; the latter influence only keeps them in readiness and health to obey the dictates of the will. This general influence of the spinal chord, however, may occasionally be, and in these instances is, limited to one muscle; for in the cases alluded to the foot was neither inverted nor everted, but held in a straight extended position, and after the division of the tendon, the restoration of the foot to its natural position easily followed, without its having exhibited any tendency to deviation on either side during the time of treatment.

In all cases, from whatever cause they originate, more or less atrophy of the entire limb will be found, according to the length of time the deformity has existed; and even in incipient cases, in which, before the contraction is confirmed, and previous to paralysis of the flexor or flexors, you may, by

appropriate remedial measures, have removed the exciting cause; yet even in these cases I have always found the affected limb smaller than natural, as well as smaller than its fellow; for the perfect limb may be said to be larger than natural in consequence of being compelled to do double duty, and the muscles thereby becoming more strongly developed. The weakening influence of the contraction in the affected foot at an early period becomes permanent; the patient possessing one strong and useful limb, avoids, as much as possible, the use of the infirm member.

In those cases where paralysis of one or more muscles exists, of course there can be no chance of re-development of the member; the patient must then rest satisfied with the free motion of the joint and artificial support, as at present we are aware of no cure for paralysis; whereas in those cases where contraction is found without co-existing paralysis, whatever the age of the patient, we find that after the removal of the contraction, and of all impediments to the motions of the joints, the limb will recover to a great extent its natural size by a re-development of the muscles from exercise. I have observed this effect to occur in two cases, each at the age of 38 years. In both the contraction had taken place in infancy, and every mechanical and other means had been resorted to without success. In one the heel was elevated three inches above the ground, in the other not more than half an inch; the anterior tibial muscle in both retained its power of motion after the operation and flexion of the foot, and both patients were enabled to use the foot with perfect ease and comfort without assistance from artificial support; the limbs, too, increased in size and firmness, and the pain and lameness were entirely removed.

The cases I have described hitherto have been examples of perfect talipes equinus, in which the foot does not deviate to either side; but it frequently happens that in consequence of the loss of power, or paralysis of the flexors of the foot, a weakness of the lateral ligaments ensues, from constant stretching occasioned by the weight of the body in walking; and great pain is frequently experienced from treading on any uneven surface, such as a pebble, or other inequality, so much so that I have known a patient, after having made one unfortunate step of this kind, unable to walk for the remainder of the day—the contact of the foot with the ground occasioning a sensation as if the ankle had been dislocated. This stretching gradually increases the length of the passive attachments of the joint, until the patient walks on the under and outer surface of the fifth metatarsal bone. The variety of talipes equinus thus produced is

called *talipes equinus varus*; and the foot occasionally becomes so completely inverted that the patient walks on the dorsum of the metatarsus. Of course the ligaments on the

Fig. 5.

Cast of a patient, 18 years of age, in whom the foot at first presented the appearance of talipes equinus, but, from the cause mentioned, the sole is directed upwards, the dorsum downwards.

dorsum are also greatly stretched; but the deformity, although so frightful in appearance, is generally very manageable; though the under margin of the foot becomes closely approximated to the internal malleolus, yet will it generally be brought to yield, and to assume its natural position, by the division of the tendo-Achilles alone. It is not, as you will more clearly perceive hereafter, the amount of deformity, so much as its cause and nature, which occasion difficulty in the treatment.

A contraction of the gastrocnemius, if it is impossible to flex the foot beyond a right angle, I should consider as incomplete talipes equinus, and you will find this species of the deformity vary from that point to the extreme form which I have before described in complete talipes equinus; even this modification, namely, a contraction of the gastrocnemius, will occasion the patient great inconvenience and pain, as in every step the weight of the body is thrown, when the other is carried forward, on the extremity of the metatarsal bones, and frequently the foot will swerve to either side, if on any but a perfectly flat surface. The lateral ligaments in these instances are elongated, and the foot, if suspended above the ground, will appear as if its attachments were separated, when the will is not in active exercise; that is, when the muscles are in a state of repose. In almost all cases, and in every case without exception where paralysis exists, the natural temperature of the limb is reduced, and it becomes unable to resist the effect of changes of temperature. The limb appears innervated, which arises, I have no doubt, in a great measure

from its passive condition, as well as from a weakened state of the nerves themselves, both of the skin and of the moving powers. From my observation I believe that the relative positions and size of the astragalus and the joint retain their normal condition; although I am aware that a different opinion has been entertained, for in no case that has yet appeared have we failed to restore the position of the foot.

In adult cases that have arisen during infancy, in which the patient has been compelled to use the limb daily in obtaining his livelihood, there is in all probability a thickening of the synovial membrane and ligaments, and diminished size and capacity from a continuance in one position; the synovial secretion also must be less abundantly generated, not having been required to lubricate the joint, inasmuch as there has been no motion; hence the grating often felt after the foot has been placed in its normal position. Both of these circumstances would act as impediments to the return of the astragalus back into the articular cavity, but this difficulty does not constitute an alteration in the relative size of the astragalus and its articular cavity. The cavity of articulation is so beautifully adapted to its use, that in the healthy and natural state but little room is left beyond that which is actually necessary for the free motion of the joint: were it not so, dislocation would be a most frequent occurrence, whereas this accident is impossible without fracture of the fibula.

Treatment.—In every case where the contraction evidently and positively exists, I should adopt and recommend section of the tendo-Achilles; an operation so simple, so comparatively devoid of pain, and so delicate, that it can scarcely be called one; no risk is incurred beyond that appertaining to the slightest wound, and so morally and practically certain are its effects, that I have no chances of injury, no contingent evils, to lay before you for investigation. Here we have divided some hundreds of tendo-Achilles, in every variety of deformity, and as yet we have experienced no unfavourable result; therefore as this tendon is the great cause of resistance, whenever you find it contracted, I would advise division.* The operation is thus performed: let the patient be placed horizontally on his face: let an assistant grasp the leg by placing one hand under it, and the other on the anterior part of the sole of the foot, holding it firmly; by these means he will obtain entire control over it: let him keep the tendon upon the stretch by endeavouring to flex the foot: you then feel the outline of the tendon, introduce a straight narrow sharp pointed knife through the integument, and beneath the

* This operation of dividing the tendon has been long practised by veterinary surgeons.

tendon, having its flat side in contact with the under surface of the tendon. After you have passed it from one side to the other (without, however, puncturing the skin on the opposite side,) turn the sharp edge of the knife towards the tendon, and by gently depressing and raising the handle alternately, you will divide the tendon transversely from the internal to the external surface, taking care not to lacerate or penetrate the skin beyond the point of puncture. Use no violence or sudden effort; let your incision be made with firmness, but quietly and with care; for in my opinion the professional man who values his own conscience and the welfare of his patient will never, for the sake of a few seconds of time, or for the vanity of making "an impression," neglect the ordinary precautions which experience teaches us are necessary even in the slightest operation which the hand of the surgeon is called on to perform. After the division (which is merely followed by two or three drops of blood,) has been effected, you will place a piece of lint over the puncture, and keep it down by adhesive plaister; then apply carefully, and without any undue pressure, a bandage of flannel from the toes to the calf, supporting the foot by a padded straight splint. Let the patient be placed on a bed or couch, either in a horizontal or sitting posture, with the leg supported on a slightly raised pillow, and the knees flexed, taking care that the temperature of the limb is kept up by sufficient covering; for I need not inform you that if the temperature is below the natural standard, the restorative process cannot go on. I have known a case where, from the fear of inflammation, cold lotions were applied after the division of the tendon; the consequence was inflammation and suppuration. You must be guided by the sense of touch as to what quantity of covering is required, and if one blanket is not sufficient let the limb be enveloped in two or more. Do not interfere with the diet of your patient, or in any way control him except to require "rest." At the end of three or four days you will find by these means that the two divided ends have united, and that the orifice of the puncture is healed; you will then carefully bandage the limb, and place it (in the same position in which it has remained both before and since the operation,) in the instrument for the extension of the foot*. If the contraction is slight, the patient young, and there is great mobility in the joint, you must be slow and cautious; for by hurrying it, the new uniting medium becomes too rapidly elongated, and great and continued weakness is the result. In the case alluded to in my former lecture the patient not only ex-

* Either Stromeyer's foot-board, or Scarpa's shoe.

perienced great weakness, but a much worse deformity was produced than had before existed, inasmuch as the heel was at first tightly held by the contracted muscle, and the little patient could walk with firmness, whereas afterwards, from the uniting medium having been too much elongated, and from paralysis of the anterior tibial, the foot became as it were comparatively unattached, and yielded to such an extent that she now walks almost on the internal malleolus. The attempt, therefore, in weakly subjects, to place the foot in position immediately or shortly after the operation, by hastily proceeding to extension, as has been done by some, is a mode of treatment unscientific, and entirely destructive of the principles upon which the operation is founded. For its objects are two-fold; first, to overcome the resistance, and secondly, to preserve entire the integrity of the divided muscle, and thus to render it useful after the foot is restored to its position. You will, therefore, proceed with caution. In adult cases of long standing, however, you will not run this risk of the great elongation, as there will be found other resistance besides that of the contracted muscle alone. Here you will also have to contend against more or less pain, and to proceed very slowly, not from the fear of too rapid a progress, but from the resistance in the joint, and the tenderness experienced by the patient, which is occasionally most acute, on every increase of the flexion; and in cases arising from rheumatism, from scrofulous inflammation and from cicatrix, the progress of the extension will require all the patience and perseverance you can command. The pain is occasioned by the return of the astragalus into the articular cavity, and is complained of principally at the front of the joint.

You will occasionally find, as the foot becomes flexed, that it will deviate either to one or the other side; most frequently it will *erect*, forming a sort of talipes valgus; and upon examining the tendons, the peronei will be found contracted. If, however, it should *invert*, the posterior tibial will be the most probable cause. In either case division of the tendon must be resorted to, or the patient will be thrown either on the internal or external side of the foot, according to the state of the respective muscles. You will not be enabled at all times to discover this tendency previous to the division of the tendo-Achilles. Occasionally, however, you will find these tendons, viz. of the peronei and the posterior tibial, tense in a simple talipes equinus, upon a forcible attempt to flex the foot. If this tension continues after keeping up the forced extension for some minutes, you may be nearly sure that the tendon is contracted; and I would advise division at the same time that the

Achilles tendon is divided. It is seldom requisite to divide either the plantar fascia or the flexors of the toes, although both appear sufficiently tense and contracted previous to any operation. You will find that the arch of the foot will come down when the foot is flexed, and that the toes will assume their natural position—at least, as a general rule. Should they not do so, the division of either, or of both of the tendons, may be afterwards effected; the method of which operation I shall describe in detail, when I come to consider those deformities in which they most frequently require division. After the foot is flexed you may allow the patient to use it; and that he may do so with comfort and safety, we must adopt the same means used by Delpech, viz. a boot and support. The foot will thus be maintained in position, at the same time that the patient is enabled to take exercise. The support will require a stop-joint at the ankle, to prevent extension beyond a right angle until all trace of contraction and tendency to any recurrence of it shall have disappeared.

CASE OF

HÆMORRHAGE OF THE LIVER.

By JAMES ABERCROMBIE, M.D.

Fellow of the Royal Medical and Chirurgical Society, &c.

COMMUNICATED BY

JAMES COPLAND, M.D., F.R.S., &c.

(For the Medical Gazette.)

MRS. M'KENZIE, æt. 35, a lady of spare habit, of sallow complexion, and who had spent several years in India, suffered much during the last two months of pregnancy from dyspepsia. My attendance was repeatedly requested during that period, and relief was usually afforded her by mild aperients of magnesia, rhubarb, and ginger, or Murray's fluid magnesia, or the use of the liquor potassæ in milk or in some bitter infusion as a vehicle.

On the 28th of September, 1841, at 2 P.M., I received a hurried call, when I found her complaining of pain in the epigastric region, accompanied with a sense of distension, belching of flatus, and an inclination to vomit: she had no attending fever, nor was the pain constant, but returning at intervals, and evidently relieved by pressure. Having had frequent attacks of gastrodynia on former occasions, she, of her own accord, had immediate recourse to pressure for relief; and placing a silk

handkerchief round her body she desired one of her servants to pull it as tight as she possibly could. The wish was complied with, but to an extent that made me fear some injury under existing circumstances. I therefore begged it might be removed. I then prescribed for her a draught composed of Calcined Magnesia, Liquor Opii Sedativus, Spt. Ether. Sulph., and Aq. Cinnamomi, to be taken immediately, and ordered hot fomentations to the epigastrium. By these means the pain gradually abated, and, on calling to see her in the evening, she was quite relieved. From some particular sensation, however, she observed that she was apprehensive her labour was approaching. About ten o'clock she fell asleep, and rested composedly until two, when she awoke, as she had anticipated, with labour pains; and shortly after the membranes gave way. About half-past four I was sent for. I found the breech presenting, and already resting on the perineum. In twenty minutes the child was born (it was in a state of asphyxia, but by the use of the ordinary means was soon recovered). The placenta followed in about a quarter of an hour, and the uterus contracted readily. I remained with my patient fully half an hour, and finding everything going on well, I retired into an adjoining room. I returned in about twenty minutes, when, to my surprise, I found her with a fluttering pulse, much oppressed, with anxious breathing, and complaining of pain in the right hypochondrium and right side of the heart. Without considering the pain to which she directed my attention, I concluded that she was flooding. On making the necessary examination, however, I found the uterus well contracted, and the discharge outwardly very moderate. She soon became quite cold and clammy; complained of noise in her ears and dimness of sight, and expressed herself as dying. I sprinkled cold water quickly upon her face, applied stimulants to the nostrils, and administered immediately 35 drops of laudanum with a little brandy. Conceiving at the same time that she might be of that peculiar constitution that could not bear with impunity the loss of the smallest quantity of blood, and seeing the necessity, whatever might be the cause of the collapse, to prevent any further drain from the

system, I ordered cold applications to the vulva and lower part of the abdomen, and continued the use of them until the discharge was almost completely suppressed. I continued giving her brandy and water from time to time, and as she still remained very cold, I ordered stone bottles of warm water to be placed all round her body, and as near as could be done with safety. Notwithstanding these means she did not rally in the least, and apprehensive that she was sinking, I requested a consultation; when Dr. Flick was called in. He came immediately, and after examining her minutely, gave it also as his opinion that there must be some cause, independent of parturition, to account for the serious symptoms which had presented themselves. From the suddenness of the collapse we were both disposed to trace it to a rupture of some large blood-vessel, dependent perhaps upon previous disease; this, however, was a mere matter of conjecture. Our patient now commenced vomiting, rejecting almost every thing which she took. Dr. Flick approved of a continuance of the stimulant plan of treatment, and the free use of wine and brandy; and the following mixture was prescribed:—

R Mist. Camphor. ʒvj.; Liquor Opii Sedativ. gtts. xvij.; Spt. Ammon. Arom. ʒij.; M. ft. Mist. cujus capiat cochlear. mag. duo 2nda. quaque horâ.

This treatment was continued during the whole day. Brandy and wine were given at short intervals, pure, or mixed with water or sago or arrow-root, and strong beef-tea. Much, however, was rejected, the stomach continuing irritable.

Seven o'clock P.M.—No improvement. Is still under symptoms of great exhaustion, is cold and clammy, and vomits frequently. Her only complaint now is of pain in the neck a little to the right of the spine, and which is increased by taking a deep inspiration; and she frequently requests the part to be rubbed for relief. She also still feels pain on pressure being made in the hepatic region, a little below and to the left of the scrobiculus cordis, but it is not acute.

At this period Mr. Laing was also called in consultation. He made every necessary inquiry, but after satisfying

himself fully, he candidly acknowledged that, like Dr. Flick and myself, he was at a loss to form a correct opinion of the case. He thought it, however, probable, judging from the state in which he found her, that there might have been some marked inflammation, which was passing into gangrene. With Mr. L.'s view of the case, and at the same time to allay the irritability of the stomach, it was proposed to vesicate the abdomen by the application of the Tr. Lyttæ Acetosa; and the following powders were prescribed:—

℞ Hydr. Submur. gr. x.; Pulv. Opii, gr. j.; Sacch. Alb. gr. iv.; M. ft. pulv. tales iij; quorum capiat unum statim.

In other respects we decided upon continuing the same treatment, lessening only the quantity of stimulus.

Nine o'clock P.M.—Somewhat improved. The stomach is less irritable, and has retained most of the nourishment (and wine, which she has taken since last visit). Simple diluents it having been observed agreeing better with her than stimulants, and remaining on her stomach more readily, it was now decided upon to discontinue the latter altogether, unless urgently indicated by a change of symptoms for the worse.

Another powder to be given at a quarter past ten.

Two A.M.—Had a little sleep after taking the last powder. Has had once a slight return of vomiting, but no stimulants were had recourse to.

℞ Liquor. Potass. gtts. xx.; Liquor. Opii Sedativ. gtts. v.; Syrup. Simp. ʒj.; Aq. Menth. Pip. ʒij. M. ft. haustus statim sumendus.

September 30th, 8 A.M.—Continues improving: has had no return of vomiting; the pulse, though still quick, has become firmer, and she has now a comfortable warmth all over her body.

No medicine prescribed, but ordered to take beef-tea, sago, &c. as nourishment, and to use rice and barley water, or thin arrow-root, for common drink.

One P.M.—Up to within a quarter of an hour ago we had reason to think most favourably of our patient. (She had taken a good deal of nourishment, the natural warmth had still further returned, and she had considerably regained her strength). Suddenly, how-

ever, she was attacked with shivering, followed almost immediately by vomiting, and all the symptoms of collapse, as on the preceding day. The stimulating plan was immediately had recourse to again, substituting brandy almost entirely for wine (but which seemed to have no better effect in settling the stomach). The following mixture was prescribed:—

R. Ammon. Carbon. ʒss.; Spt. Ammon. Arom. ʒij.; Syrup Cort. Aurant. ʒj.; T. Opii, gttss. xx.; Aq. Cinnamom. ʒiij. M. ft. Mist. cujus capiat cochlear. mag. unum omni semihora.

Six P.M.—The vomiting continues severe, and she has rejected almost every thing since last visit. She is cold, and bathed with a clammy sweat; the pulse is very frequent and feeble, and she has occasional singultus. The uterus to outward feel is apparently of the natural size, and the lochial discharge scanty.

Cont. Mist.

Eleven P.M.—The stomach continues irritable, the patient retaining what she takes only a few minutes. Her strength is rapidly declining.

Cont. Mist.

Two A.M.—Exceedingly restless, turning about frequently from side to side, and talking incoherently. Pulse scarcely perceptible. From this time she gradually sunk, and expired without a struggle a little before eight o'clock.

Appearances on a post-mortem examination of the body eight hours after death, on the 1st of October; and which took place in the presence of Dr. Davidson, of the Bengal Medical Service, Mr. Laing, Dr. Fleck, and Mr. Brown, medical practitioners.

The abdomen outwardly was soft and of natural appearance, and the uterus was felt through the parietes, of the ordinary size on the third day after delivery.

On laying open that cavity, the caput cæcum, and a small portion of the ascending colon, were observed to be of a dark colour, nearly resembling gangrene, but evidently dependent on venous congestion. On the liver a large sac presented itself, occupying the superior and anterior surfaces, which burst on an attempt being made to remove the organ, and discharged a very considerable quantity of blood, I should

think about two pounds, both in the fluid and coagulated states: two small lacerated openings, about an inch apart, were discovered in its substance, through which the blood had escaped from a branch of the vena portæ, and the sac proved to be the peritoneal covering, which had been detached by the blood effused. The organ itself was throughout diseased, of a mottled appearance when cut into, and unusually soft, breaking down under the finger by the slightest pressure: the only part to be considered healthy was the margin. The uterus was in a perfectly sound state, as were all the other viscera both of the pelvis and abdomen.

OBSERVATIONS.—The *causa proxima* mortis in this case was the hæmorrhage from the liver, but when that took place must be a matter of conjecture. It might have happened the day previous to her confinement, when she was attacked in the manner described, and had recourse to tight bandaging for relief; in which case the effusion of blood to any extent was probably prevented by the pressure of the gravid uterus, until such time as it was emptied of its contents, and had contracted. Or—and this I confess I think more probable—it might have occurred during labour, and the effusion have been going on gradually until about an hour after the process was completed, when it began sensibly to affect her strength. The peritoneum having remained entire after the rupture took place, will readily account for the length of time the patient lived after so serious an occurrence.

This case is of great interest, and, so far as I am aware, there are only two or three on record which at all resemble it. One is related by Andral, and quoted by Abercrombie in his work on *Diseases of the Abdominal Viscera*; another is recorded by Sir Gilbert Blane (*Transact. of a Society for the Improvement of Med. Knowledge*, vol. ii. p. 18); and in this case the hæmorrhage appears to have been consecutive on changes in the liver, similar to those observed in the case just related. It is remarked by my friend Dr. Copland, when treating of Hæmorrhage of Liver (*Dict. of Pract. Med.* vol. ii. p. 730), “that when the blood is effused into some part of the substance of the liver, producing what

French pathologists have termed apoplexy of the liver, the extravasation has been consequent, either upon passive congestion of the organ, owing to impeded circulation through the heart, aorta, or lungs; or upon deficient tone of the capillaries of the liver, or softening of the part in the seat of the hæmorrhage." I perfectly agree with what Dr. Copland subsequently adds:—"Hæmorrhage from the liver is most frequently caused by external injury and rupture of the organ. When the liver is congested, and at the same time softened—changes occasionally produced in humid and miasmatic situations, either primarily or in connection with adynamic remittent or intermittent fevers—comparatively slight external injuries have ruptured this organ, and caused fatal hæmorrhage into the abdomen." The case now related would appear fully to illustrate the justice of this statement.

Cape Town, Cape of Good Hope,
May 1843.

ON THE PATHOLOGY AND TREATMENT OF OVARIAN DISEASES;

WITH CASES.

By DR. SAMUEL J. JEAFFRESON,
Physician to the Chelsea, Brompton, and Belgrave
Dispensary, &c.

[Continued from p. 650.]

The prognosis to be given in cases of ovarian disease may be considered in two points of view: first, as respects the chance of permanent cure; and, secondly, as to the probable duration of life and degree of suffering to which the malady is likely to expose the patient. It is somewhat premature, in this place, to speak of the probabilities of permanent cure before the different methods of treatment have been examined into, and the prospects which they hold out have been discussed. Setting aside the removal of the diseased mass, an operation lately revived, it must, however, be confessed, that no plan of treatment, with which I at least am acquainted, holds out any certain hope of effecting the perfect eradication of the disease. It occasionally, however, happens, that an effectual and permanent cure is due to judicious medical treatment, to natural and spontaneous processes, or to accidental causes. Of the spontaneous

form of cure, one instance has been already detailed in Case V. Cases of this kind, however, often require great assistance, and judicious management on the part of the medical attendant, to conduct them through so perilous a crisis to a favourable issue. Many cases somewhat similar to the one which I have related are on record, in which the walls of the cyst have formed attachments to the bowels, or some other natural outlet, and ulceration, with escape of the fluid or grumous contents of the tumor, and permanent cure, have ensued. In some few instances a similar mode of cure, permanent or temporary, has been effected by adhesion of the cyst to, and ulceration through, the abdominal parietes. Dr. Ramsbotham states that such openings generally occur at the umbilicus, and relates a very interesting case which occurred in the practice of his father, who, it appears, had been for some time attending this lady for ovarian enlargement. The age of the patient was 40, and Dr. Ramsbotham's father was suddenly summoned to her assistance, in consequence, as it was said, of the body having ruptured.—He found the floor of the apartment deluged with aqueous fluid, that had issued from an ulcerated orifice at the umbilicus. The patient was faint, exhausted, and in imminent danger. A bandage was applied, and cordials were administered. She rallied, and lived afterwards for eight years.

Another most interesting case is related by Dr. Seymour as having occurred to the celebrated Dr. Mead, which should make us cautious in pronouncing a hopeless opinion of similar cases. The patient consulted Dr. Mead for an enormous ovarian tumor of the fluid character. He pronounced her case as hopeless, and considered her too much reduced even to bear the temporary relief of paracentesis. A few days afterwards, however, the tumor ruptured through the abdominal walls near the umbilicus. The same utterly hopeless opinion was still adhered to by the Doctor, in which, however, he was again mistaken, for the patient rallied and recovered.

Independently of these, if they may be so called, cures of nature, it has occasionally happened that paracentesis, which has been resorted to for temporary relief only, has been followed by

permanent cure; or that the opening made by the trochar has remained as a permanent fistulous opening, through which the contents of the cyst have drained off, and the disease has been eventually overcome.

Amongst the accidents which have given rise to the permanent cure of ovarian disease are blows on the abdomen, great fright, muscular exertion, &c. The cyst has thus been ruptured, and its contents have been allowed to escape, sometimes probably into the peritoneum, where they have been absorbed; at others into the bowels, bladder, uterus, &c. at points probably where adhesions had been long established between these viscera and the cyst, and in which the natural cure by the process of ulceration had been commenced or nearly effected at the period of the accident. I quite agree with Dr. Ramsbotham, in his suspicion that in the cases cited by Blundell and Abernethy the rupture was probably into the bladder or ureters; for it is difficult to suppose that the escape of the contents of the tumor into the abdominal cavity could be followed by immediate absorption, and an unceasing flow of the contents through the kidneys, ureters, and bladder, until its entire removal; besides which, the escape of foreign matters within the peritoneal cavity is almost universally attended by symptoms of a most formidable character. I remember one case at least on record, in which rupture of the cyst into the abdominal cavity was followed not by absorption and recovery, but by the death of the patient. In all these cases it must be remembered that the cyst remains within the abdomen, although its contents have been evacuated: the cure, therefore, cannot be considered as entirely perfect; but neither in the case above related, as occurring within my own practice, nor in other instances, have I been able to discover that there has been any return of the effusion; nor have I met with any accounts of the morbid appearances presented in such instances, where death has occurred many years after this form of cure. It must, therefore, be presumed, that the cyst becomes puckered up, and that its internal surface undergoes some changes, from inflammation or other causes, which render it no longer capable of secreting a similar fluid.

So much, then, for these forms of

cure; the contemplation of which, even as circumstances of comparatively rare occurrence, must afford some hope and consolation to the sufferer. Such results can, however, of course be predicted as possible or probable in those cases only in which the contents of the cyst are entirely fluid, or being in part solid, are found to be gradually softening, and becoming fluid. If, in addition to these circumstances, and setting aside the surgical treatment of the disease, we take into account the fact that some cases of ovarian tumor, both of the fluid and mixed form, have yielded to general plans of treatment which have effected a cure by inducing their absorption; and that we possess considerable power in promoting that process of softening of the solid portions which precedes the cure by ulceration, of which fact I hope to be able to adduce additional evidence to that already placed before the profession by Dr. Seymour; taking, I say, all these circumstances into account, the prognosis of ovarian disease, as respects ultimate cure, will not be found so entirely and utterly hopeless as it has been represented by some authors.

The second subject for prognostication is, "the probable duration of life, and the degree of suffering to which the malady is likely to expose the patient."

No one who has seen much of the disease can fail to be struck with the great variety which obtains, whether in solid or fluid forms of the tumor, in the rapidity of their growth and the degree of distress to which they give rise. As respects the mixed form of ovarian tumors (partly solid, partly fluid), to go no further than the six cases above described, we find one which has existed twenty-two years without destroying the patient, and upon the ultimate result of which it is in vain to speculate, the patient's distress and inconvenience being less, and her general health better, than when I was first consulted, now six years ago. Another case, much larger in bulk, has now been in existence twenty-five years. To set against these, two cases are related which terminated fatally within about a twelvemonth of their origin, or at least their first manifestation by symptoms. Were it requisite, more chronic as well as more acute examples might be adduced from the records of practical writers on the subject. One instance is related in

Dr. Copland's Dictionary, in which Frank states the disease to have commenced at the age of 13, and yet the patient attained the age of 88 years. As regards the fluid variety of tumor, whether unilocular or multilocular, perhaps almost equal variety obtains in respect of their duration; for whilst many instances are on record in which the first paracentesis has been speedily followed by death, or in which this has occurred without the operation having been ventured upon, others are found in which the patient has lived many years, and attained a considerable age. Not to weary the reader by a too tedious reference to cases already well known, this one example may be quoted, in which Mr. Martineau, of Norwich, tapped a woman of the name of Sarah Tippus, 80 times in the space of 25 years; the reader will also bear in mind Case III. in which the operation has been now performed thrice in 10 years, and yet the patient's general health is not impaired beyond the effects induced by the weight and mechanical inconvenience of the disease.

Independently, however, of the cures of ovarian disease which occasionally take place spontaneously, or under the influence of medical or surgical treatment, and independently also of the slow progress which the growth makes in some instances, it is frequently observed that ovarian tumors of either character, when undergoing a tolerably rapid course of enlargement, will sometimes spontaneously, or as the effect of well-directed medical treatment, experience a sudden arrest of growth, and remain for years, or even for the whole of life, stationary; and the source of no further inconvenience than what is due to their bulk.

Such circumstance I am inclined to attribute to the partial disorganization of the solid portions of the tumor, and to such changes in the character of the cysts containing fluid secretions, whether inflammatory or not, as incapacitates them from further secretion. I cannot pretend to offer any evidence in support of this opinion sufficiently strong to render it certain; the reasons, however, which have led me to it are these: that such sudden arrest of growth has been frequently observed in connection with those causes, natural or artificial, which are observed to be most efficient in promoting the process of

softening of the harder masses: such are inflammation, however set up; and the use of certain medicines, and other methods of general treatment, presently to be noticed.

It may be well, however, to state, that the impression which prevails with the members of the profession, that ovarian disease is not generally attended by risk to life, is decidedly incorrect. The ovaries, it is true, are not vital organs, and may therefore undergo an amount of disease which would be speedily destructive if situated in other parts. Taking into consideration, however, the occasional malignant nature of the affection; the frequently enormous bulk of the diseased growth, with its consequent exhausting effects, and above all the numerous morbid conditions of other parts to which it may mechanically give rise; it must be but too evident that ovarian disease is a formidable malady, and one of but too certain a tendency.

It is to be regretted that neither of the points proposed for consideration in the prognosis of ovarian disease receive much light and assistance by reference to statistical tables; for whilst the statistics of hospital practice hitherto presented to the public afford too few examples of ovarian disease to serve this purpose, the returns of mortality published by our talented and industrious Mr. Farr, of the General Register Office, are compiled from sources not sufficiently accurate as respects this one (and that too not very frequent) cause of death, to be relied upon. That such is the case may be readily ascertained by referring to the Annual Reports, in which no small proportion of the fatal cases of ovarian disease are stated to have occurred at ages in which their very existence has been denied by the most experienced practitioners; whilst on the other hand, it is more than probable that many real instances of fatal ovarian disease have been included under other heads—as dropsy, ascites, tumors, &c.

Before entering upon the subject of the treatment of ovarian disease, I shall endeavour to draw some deductions from the facts above narrated, or contained in the works of practical authors on this subject.

1st.—*Inflammation of the ovaries.*—These organs are no doubt subject to inflammation in the same way that

other parts are. Inflammation of the ovaries is probably in many instances the primary process by which those changes are effected in their structure which are afterwards recognized as ovarian tumors. Inflammation of the ovaries, in persons of a strumous habit, is not unfrequently, in my own opinion, a cause of ovarian tumor, in which case the results of the continued inflammatory action may be very like that which happens in scrofulous inflammation of the absorbent glands, namely, first intense hardening, then softening, ill-conditioned suppuration, and production of a flaky curdy substance. That ovarian tumors once formed, from whatever source, may become the seat of inflammation, is not, I think, a matter of doubt. Such process it is, in my opinion, which often gives rise to those constitutional symptoms of great danger, which have led some to suppose the disease to be of a truly malignant character, when it in reality was not so. Such process, too, has occasionally been the means of cure, by inducing general softening and disorganization of the tumor, the contents of which have escaped by adhesion of its cyst to the bowels, &c. and by ulceration.

2d. *Fluid tumor—unilocular.*—This may occur in three different ways; 1st, by effusion between the fibrous covering of the ovary and its peritoneal envelope; 2d, by one of the vesiculæ of Graaf being alone the seat of disease, in which case, as the fluid goes on to be secreted, the pressure thus induced causes partial or entire absorption and obliteration of the remaining structure of the ovary. In both these instances the fluid is usually clear and tolerably uniform in its appearance; it may towards the last become more ropy, and slightly, perhaps extremely, opaque; 3d, I believe that a tumor not originally unilocular, nor even entirely fluid, may at some further period become, so to speak, unilocular and fluid, so that it may be entirely emptied, whether discharging itself by an artificial or spontaneous opening; such process I believe to be effected by inflammation, or at least a process analogous to it, in which the harder parts of the tumor are softened, and the intervening septa which separated its various compartments are partially or entirely absorbed and destroyed.

3d. *Fluid tumor—multilocular.*—I do

not ever remember to have examined an *entirely* fluid multilocular tumor, Such, however, do occur. In all the cases I have examined larger or smaller portions of the tumor have presented various degrees of solidity, whilst others were fluid. If multilocular but *entirely* fluid tumor were a primary form of ovarian disease, I think it would be more commonly met with in post-mortem examinations; whereas in the process of softening to which I have before alluded, it will rarely be witnessed; since the active powers which are at work to convert the solid mass into fluid are equally active in destroying the barriers by which the several compartments are divided.

4th. *Mixed tumors, in which the different parts are in various degrees of solidity and fluidity.*—These tumors are invariably divided into different compartments, corresponding probably with the Graafian vesicles or corpora lutea, in which the disease originally commenced. That this is by far the most frequent form of the affection is agreed by Dr. Seymour, and most other authorities. It is more than probable that this form of disease obtains in many instances from the very first, some vesicles containing fluid, which is increased by continued secretion, without outlet; other vesicles, or probably corpora lutea, being occupied by solid deposition, which also continues to augment.

5th. The serous or fibrous investment of the ovaries, independently of the hypertrophy they undergo in the process of growth of the ovarian tumors themselves, may become the seat of various forms of morbid deposit. Such forms of disease can rarely perhaps be diagnosed during life as separate affections; nor is this probably a matter of much practical importance.

6th. *Malignant tumors, properly so called.*—Pure carcinoma, melanosis, or fungus hæmatodes, are certainly rare affections of the ovaries. I have never myself witnessed them, but should be unwilling from this reason to deny a fact resting on the authority of more experienced practitioners. Besides this, there appears no reason why these parts should be exempt from such forms of disease. Practically speaking, it is of importance to know that the diagnosis between malignant and other

tumors of the ovaries during life must be very uncertain.

7th. Hydatids of the ovaries.—I have never met with this affection. For the reasons above stated, however, I believe in the existence of the affection, though probably of rare occurrence. Care should be taken not to mistake the ordinary cysts for hydatids, an error into which I believe our forefathers to have fallen, since in the works of Morgagni, and the older authors, I find constant allusions to the presence of hydatids in the ovaries.

8th. Specific forms of tumor, not exactly malignant.—Whatever other specific forms of ovarian tumors there may be, I am well convinced that many ovarian tumors are connected with a strumous diathesis: some are scrofulous from the commencement; others perhaps not, but in their progress so modified by the constitutional diathesis as to take on morbid processes and characters in all respects similar to those observed in other scrofulous tumors.

9th. The complications of ovarian disease are constitutional states (especially strumous diathesis)—similar or different forms of structural diseases of other organs—some sympathetic derangement of distant parts—but chiefly affections arising out of the mechanical inconvenience of the tumor, amongst which may be mentioned deranged digestive organs, thoracic organs, &c.; peritonitis, and other inflammations; ascites, œdema, &c.

The treatment of ovarian disease may be divided into the palliative and curative; and these again may be considered in two points of view, viz. the measures of treatment which come fairly within the province of the physician, and those that properly belong to the surgeon. I shall commence with a consideration of the medical or general plan of treatment, and first of

Inflammatory affections of the Ovaries.

Pure inflammation of the previously healthy ovaries is necessarily an affection not to be easily discriminated, perhaps because these bodies are in their natural state very small; next, because their functions are, though highly important in the economy, not vital; and, moreover, the organ is double, and we cannot in it, as in some other double organs, pronounce with

certainty that the appropriate functions are being exercised by the one and not the other organ; and lastly, because by some extraordinary coincidence it happens that the sympathetic derangements of other parts in connection with ovarian disease are by no means so numerous and well marked as happens of some other affections. In spite, however, of these difficulties, I feel convinced that we often meet with cases, especially amongst young women, in whom some irregularity obtains respecting the menstrual functions, in females very recently married, particularly those who have married rather late in life, which upon careful examination we may fairly attribute to inflammatory affection of the ovaries, either as the whole or large part of the source of mischief. In these instances some irregularity of temperature is observed; slight increase of frequency of the pulse, though it may be very feeble; some derangement of the digestive organs, and more especially the stomach, and some symptoms of an hysterical character. There is always more or less pain, but frequently, from a too nice sense of delicacy, the situation of this pain is not sufficiently accurately explained; and this subject requires to be carefully investigated by the medical attendant, rather than to be entirely entrusted to the description of the patient. Cases of this kind have been occasionally, I suspect, overlooked as mere hysterical and nervous disorders. When, however, the great importance of the subject is considered, it will induce increased caution in the investigation and treatment of affections in the first instance, indeed, apparently trivial, but which may go on to the establishment of organic changes of the most formidable character.

The treatment required is of course of the antiphlogistic kind; but in my own experience, I should say that general blood-letting is neither so well borne, or so much required, as in many other forms of inflammation. Cupping to the lower part of the back, leeches to the sacrum, inside of the thighs, or vulvæ, are the preferable modes of bleeding. The risk of inflammation not being in the direction of the deposition of coagulable lymph, excepting where the serous envelope of the ovaries is the part affected, mercury carried to salivation is no more required

than general blood-letting; both, indeed, may be prejudicial; mercurial alteratives and aperients, followed by saline purgatives moderately used, are highly proper; and especial care should be taken to observe that the colon be not loaded with hardened fæces, which may keep up a great source of local irritation. Abstinence from stimulating food and drink, and frequent recurrence to the horizontal posture, should be carefully enjoined. The emetic tartar, combined with the salines, in moderate doses, so as to affect the skin and produce slight nausea, will be found useful. Tepid hip baths and tepid narcotic fomentations, or enemata, especially the conium, have been recommended by Dr. Seymour, and I can bear testimony to their beneficial effects in several instances which have come within my own observation. Above all, if the patient be married, a temporary abstinence from the nuptial bed should be strictly enjoined.

The pain and other symptoms removed, and the natural performance of the menstrual function (if previously deranged) being restored, better diet and light tonics, especially the milder preparations of iron, may be advantageously employed. Now this class of cases should be carefully distinguished from those in which absence, irregularity, or other morbid conditions of the catamenia, are dependent upon a deficiency of richness and fibrin of the blood, and lax conditions of the muscular fibre generally, and with them probably of the natural textures of the uterus and ovaria, in which cases a tonic and invigorating treatment from the first, even with the use of general and local stimulants, may be advantageous, care only being taken to correct the secretions of the great secretory glands, and to secure the due evacuation of the lower bowels.

Ovarian tumors once formed, from whatever cause, may become the seat of inflammation. The inflammation in this instance may principally affect the investing membrane, or the body of the tumor, if solid and organized. Inflammation affecting either the body or, investing cyst of an ovarian tumor is not, I believe, so readily to be extinguished as it may be in some other parts of the human frame: to this conclusion I have been led by the observation of several cases both in my own

practice, and from the records of other practitioners, and it seems further borne out by the Cases No. IV. and V. The rationale of this circumstance may probably be explained in the fact, that the cyst, constantly stretched from within, and exposed to pressure, friction, &c. from without, is thus placed in the conditions most favourable to keep up inflammatory action when once established; whilst the organized structure of the tumor itself, somewhat similarly situated as regards pressure and other sources of irritation, is perhaps less susceptible of the influence of remedial measures of the antiphlogistic character, than other previously healthy organic structures.

These circumstances are, however, the less to be regretted, in that these forms of inflammation require rather to be kept within bounds, than to be eradicated and extinguished. Allusion has been already made to the opinions of Dr. Ramsbotham, that the growth of ovarian tumors is sometimes arrested by the formation of extensive adhesions between the cyst and the neighbouring parts; such adhesions must of course be due to inflammation. I have already given my own reasons for doubting the accuracy of this observation; but at the same time it is hardly necessary for me to observe, that the opinions of Dr. Ramsbotham deserve our highest respect and consideration. It is not necessary here to do more than refer to the position formerly assumed, that inflammation, or a process analogous to it, frequently induces softening of the harder portions of the tumor; and that this process, together with adhesion of the cyst to neighbouring parts and ulceration, have thus constituted the means of permanent cure, or great temporary relief of the affection. In these instances I have invariably observed a rapid increase in the growth of the tumor, and constitutional symptoms have occurred of a formidable and often most dangerous character. The reader may find several cases in point in the works of Dr. Seymour and other authors, and is referred also to Cases No. IV. and V.

Sufficient inducement therefore exists to lead the practitioner to confine himself to the adoption of such measures of general and local treatment as shall be required to keep inflammatory action within due bounds, and to miti-

gate the sufferings of the patient, and ward off the more imminent dangers by which life may be threatened. It is hardly necessary to enumerate the measures in which this practice consists, which must be conducted according to the peculiarities of each individual case. The means to be adopted will readily suggest themselves to every practical man, whose skill and tact will be chiefly tried in the timeliness of their application, and the extent to which it may be required to use them.

[To be continued.]

ABSURDITY OF MODERN DOCTRINES IN REGARD TO STHENIC & ASTHENIC DISEASES.

To the Editor of the Medical Gazette.

SIR,

As it is not usual for medical authors, or indeed for any writers zealous for the truth of what they advance, to refuse to say where the evidence on which they rely may be found, I am disposed to look upon the silence of Drs. Crawford and Tweedie, as well as that of Dr. Copland, as a tacit confession that no evidence, to the extent which is really necessary to maintain their opinions, has ever been placed on record. I shall, therefore, consider them as having adopted the views contained in their article on Inflammation, not because they admit of being proved to be true, but because they seem to afford the easiest and most satisfactory solution of the phenomena attendant on the inflammatory state; because they help them over what has hitherto been the pons asinorum of all physio-pathological writers from Mr. Hunter to the present time, viz., the difficulty of explaining the difference between active and passive inflammation.

I think it will be easy to show, in a somewhat novel manner perhaps, though not the less true on that account, that the doctrines alluded to do in reality involve greater difficulties than they explain, and in fact lead to absurdity. According to these doctrines there are two great classes or divisions of diseases, the one belonging to what is called the hyperæmic, and the other to the anæmic condition; the state of health being somewhere

between these two opposite conditions; the former being an exaltation above, and the latter a depression below the state of health. It is further taught, that out of each of these two conditions spring peculiar diseases which terminate alike in death, and that the object of the antiphlogistic treatment is to lower and bring down the sthenic diseases to the standard of health. Now if we were to attempt to form a scale according to these doctrines it would be necessary to place death at each end, and health in the middle, thus:

By exhibiting the modern doctrines in this point of view, their fallacy is seen at a single glance; because, inasmuch as <i>sthenic</i> diseases sooner or later before arriving at the point of death go down the scale, and become <i>asthenic</i> without passing through health, there is in reality no termination to sthenic inflammatory diseases in the direction above health. Thus we see that although such a scale would be in accordance with modern science, it cannot be formed at all, because it would be contradicted by the daily experience of every practical man. It follows, therefore, that the idea of a person being ill, and yet at the same time being in a state exalted above that of health, is absurd. If this be the case, how can we be surprised at seeing it at length acknowledged with sorrow that "scientific men are not practical?" The fact is so, and the reason, to my apprehension at least, clear enough—the science is not sound; and the only wonder is that it has not been admitted before.	Death.
	Different degrees of hyperæmic diseases.
	Health.
	Different degrees of anæmic diseases.
	Death.

I would now, sir, beg to draw your attention to a scale which can be formed, and which shall be exactly the reverse of the preceding, viz. in opposition to the doctrines of the schools, but in strict accordance with fact and observation. Perfect health and complete death are the two extreme states in which it is possible for a man to be; no one can be beyond, that is, either above or below these limits, because no person can be *more than quite well* on the one hand, or *more than quite dead*

on the other; consequently, *all disease must necessarily be intermediate between health and death*. When a person is ill, therefore, he falls below health, and drops down through the scale more or less rapidly, according to the degree and severity of his illness, whatever it may be, so that a scale formed according to such views would stand thus:—

Health being at the top, and death at the bottom. These are plain and simple truths which can neither be perverted or denied; and I would beg your special attention to them, on account of their practical bearing. The most direct and immediate inference to which they lead is, that nearly the whole of the doctrines relating to the antiphlogistic treatment of diseases must necessarily be erroneous; for when a person is ill (e.g. violent inflammatory fever) he has fallen down the scale; he does not require to be antiphlogisticated, and bled and lowered still <i>nearer to death</i> , but to be restored and <i>raised up</i> to the standard of health. Sooner or later, therefore, the antiphlogistic method must give way to an improved system of therapeutics; and when this shall be accomplished, then, but not till then, will the reproach of not being practical cease to apply to the scientific practitioner. There is much, however, to be done before this can be effected, for though any folly flies through the world like wildfire, truth still has to work its way by slow degrees. The first step to be taken consists in establishing sound principles, for no stream can be clear in its course which is muddy at the fountain-head, and it is on this account that I have called upon Doctors Copland and Crawford and Tweedie to produce their authorities.	Health Not well. Ill. Very ill. Extremely ill Death.
---	---

I have the honour to be, sir,
Your obedient servant,
J. W. EARLE.

Cheltenham, August 27, 1844.

RETROVERSION OF THE UTERUS

IN ITS UNIMPREGNATED STATE, WITH
PROLAPBUS OF THE BLADDER.

By JAMES WHITEHEAD, M.R.C.S.E.
Surgeon to the Manchester Lying-in Hospital, &c.
(For the London Medical Gazette.)

WRITERS on midwifery who have described retroversion of the uterus, speak of it, so far as I have been able to ascertain, as occurring principally during the period of utero-gestation; and that, at a certain stage of the process, by the efforts of nature alone, and sometimes by manual assistance, it either rises into the cavity of the abdomen, or the premature expulsion of its contents enables it to resume its natural position in the pelvis; after which, sudden cessation of all disturbance ensues, and the patient is at once restored to health. It is stated that sometimes a portion of the uterus continues to occupy its abnormal position till gestation is completed, so much of it only ascending into the abdominal as cannot be contained within the pelvic cavity. Cases are recorded of the displacement having been occasioned by scirrhus of the uterus, morbid growths within its cavity, and enlargement from various other causes; and even where the organ had undergone no alteration whatever, the pelvis and neighbouring viscera remaining also unchanged. Roche and Sanson speak of it as if it were of frequent occurrence while the uterus is unimpregnated and healthy, but specify no cases; while pathologists of our own country regard it as a rare occurrence under any circumstances, making but slight allusion to it in the latter state. I know no reason why it should, on the average, be more frequently met with in France than in England; and if the statement of these eminent pathologists be correct, the case has probably, on some occasions, been overlooked by us. It certainly does appear impossible, taking into account the relative dimensions of the uterus, on the one hand, and the cavity which contains it, on the other, that the kind of displacement in question, the organ being unimpregnated and healthy, could be productive of any noticeable inconvenience to the other pelvic viscera. Its enlargement, therefore, whether from the presence of an ovum, or

from diseased action, would seem necessary to the development of those functional disturbances which render the case so important in its character, and occasionally so serious in its results. To those who have met with it during pregnancy only, the following case may be of interest, as it shows that not only does retroversion of the uterus sometimes exist while the organ is unoccupied, and, so far as can be ascertained, of no more than its healthy size, but also that a train of most tedious and troublesome symptoms, inducing a state of imminent danger to the patient, may supervene thereupon. The reader will probably arrive at the conclusion, however, that the accident at commencement occurred in the usual way, the uterus remaining, after its contents were expelled, unreduced. As the real nature of the case was for a time obscured by symptoms which at first were believed to be idiopathic, I prefer giving the principal part of the account as put down, during its progress, in my notebook.

On the 26th May, 1844, I was requested to see E. O., on account of suppression of urine. She is a married woman, 30 years of age, mother of one child; greatly emaciated, and of relaxed habit. The abdomen was found considerably enlarged, tense, and extremely painful; uterus prolapsed; the portion extruded beyond the os externum vaginae in size equal to the half of a pessary of the largest dimensions, being œdematous, excoriated, and immoveable. Her sufferings, contrary to expectation, were but very slightly mitigated by emptying the bladder, the urine evacuated amounting to not more than a pint. After this procedure, the most urgent symptom appeared to be smarting at the seat, which was so distressing, that the patient believed it to be keeping up all her other sufferings. It had troubled her only during the last twenty or twenty-four hours, and was accompanied by frequent but ineffectual efforts to empty the bowels. Although generally costive, the bowels of late had acted at least once daily, the effect of aperient medicine. A gentle effort was, in the next place, made to reduce the prolapsus; but the parts could be no more than simply touched, on account of their extreme soreness, and the pain

over the lower part of the abdomen, and along the course of the rectum, produced by the slightest impulse given to them. Below the orifice of the uterus, which was situated at the lower third of the extruded mass, the finger could pass only a short distance within the vagina, owing to its lining membrane being folded down; and at the floor of the passage, betwixt it and the bowel, was felt a hard painful tumor, of considerable size, which appeared to be formed of hard faeces accumulated in the rectum. The catheter, on entering the bladder, would pass only towards the right side, in a direction towards the right sacro-iliac joint. The iliac and hypogastric regions, so far as could be ascertained by the slight pressure the patient was able to bear, were hard, irregular, and doughy to the feel. The stomach had been irritable all day, rejecting every thing taken; tongue red and glazed, furred at its back part, raw at its tip and edges; pulse small and feeble, beating upwards of 140 per minute; skin hot and parched; thirst insatiable. For two or three years she has been troubled with a bearing down of the womb; has had several miscarriages, but is not pregnant at present. Feeling no doubt that all the above-named symptoms owed their existence to accumulation of faeces in the lower bowels, with inflammation of the mucous tissues, the following plan of treatment was adopted:—Ordered, that eight leeches be applied to the hypogastrium, to be followed by fomentations and a poultice; to take a pill containing two grains of calomel and the same quantity of opium at bed-time, and an ounce of castor oil early the following morning. The ingesta to consist entirely of gruel, barley-water, and linsed infusion.

27th, P.M.—Catheterism was performed morning and evening, the urine evacuated each time amounting to twelve or fourteen ounces. The pain and tension of the abdomen have been somewhat relieved by the leeching, &c., but the fulness remains. There has been no action on the bowels, but frequent attempts have been made, accompanied by excruciating tenesmus. The rectum is evidently impacted with faeces, as appears from increased tumefaction at the back part and floor of the vagina. On examining the situa-

June 1. Catheterism morning and evening. The patient is comfortable. The bowels have acted freely, and dry acybalous feces have been voided in quantity sufficient, exclusive of the liquid part, to half fill a chamber vessel of ordinary dimensions. The uterus and bladder maintain their relative position as before; the protruded parts still irreducible. As the tumefaction at the floor and back part of the vagina remained undiminished, an attempt was

made to remove the contents of the uterus by the use of a syringe. The uterus was not moved, and the contents were not removed. The patient is comfortable. The bowels have acted freely, and dry acybalous feces have been voided in quantity sufficient, exclusive of the liquid part, to half fill a chamber vessel of ordinary dimensions. June 7. Catheterism morning and evening. The patient is comfortable. The bowels have acted freely, and dry acybalous feces have been voided in quantity sufficient, exclusive of the liquid part, to half fill a chamber vessel of ordinary dimensions. The uterus and bladder maintain their relative position as before; the protruded parts still irreducible. As the tumefaction at the floor and back part of the vagina remained undiminished, an attempt was

made to ascertain its nature by introducing the finger within the rectum; but this could not be endured. Fomentations, and the mixture and pills, to be continued. An ounce of castor oil, with twenty drops of laudanum, to be taken at bed-time.

2d.—Catheterism morning and evening. Has passed a restless night, on account of tenesmus and frequent purging, accompanied by severe gripping pain; dejections copious and scybulous; abdomen less tender on pressure; colon still distended with feces in greater part of its course, with here and there a little flatus. Remedies to be continued, and an ounce of castor oil with laudanum early in the morning.

3d.—Catheterism morning and evening. The purging has continued through the night, but is now somewhat abated. An incredible quantity of dry, hard, knotty feces have been voided, resulting in great relief to the patient; tenesmus still very distressing; tongue not so red; thirst a little abated; pulse 126; countenance less anxious. The abdomen, although considerably enlarged, is not so painful; the prolapsus still irreducible, but pressure upon it produces much less of suffering than it did formerly. The tumefaction before alluded to, however, being scarcely if at all diminished, examination per anum was again attempted, and with success. The lower part of the rectum was empty. At a point opposite the junction of the coccyx with the sacrum, the finger was arrested by a hard oblong tumor lying across the bowel, reducing its capacity at this part to a mere fissure; beyond this it was impacted with hardened feces. On attempting to raise this tumor, which was but very slightly moveable, the impulse was communicated to the bladder, and to all the protruded mass, and occasioned considerable pain about the sacrum, hips, and hypogastrium. Entertaining from these signs a belief that the tumefaction hitherto regarded as a collection of feces must be the uterus, further and more careful examination was made within the vagina, and the outlines of this organ at once clearly defined; its fundus below, its lateral margins converging upwards and reaching to the symphysis pubis, thence making a rectangular turn forward. All further doubt on the subject

was put at rest by exploring its interior with a catheter. The instrument, one of the long elastic kind, with its ordinary curve considerably increased (the female catheter having been found too straight), passed first in the direction before indicated, namely, backwards and upwards for nearly two inches; this was the extent to which the straight instrument formerly used was passed, having been arrested, not at the fundus uteri, as was supposed, but at the sharp turn which the passage makes at this part. The catheter then took a downward direction towards the hollow of the sacrum, and lastly forwards to the fundus uteri, where its point could be felt by the finger when rested against the tumor, either within the rectum, or at the floor of the vagina, behind the fourchette. The length of the portion of catheter passing within the uterus, measuring from the external orifice, is four inches and a half, giving to the womb the appearance of being considerably elongated. This, however, there is great reason to believe, is not the case, as, upon closer inspection, the opening leading to the uterus (and probably the canal also to some extent), is evidently not the os tincæ, but a fold of vaginal membrane pushed down by the bladder, of the descent of which organ I did not become fully aware until to-day. This oversight was owing, in great measure, to the objection the patient evinced to any exposure during examination, and also to the œdematous and excoriated state of the parts, rendering them so irritable as to forbid, for some time, the necessary manipulatory interference. Its earlier discovery, however, could have made no difference in the treatment. It will be unnecessary to fatigue the reader with further detail of the patient's daily progress; it may be sufficient to say, that from this date her improvement, though slow, was gradual and uninterrupted; but she could not evacuate the bladder by her own efforts until the thirteenth or fourteenth day; nor did the bowels seem to be fully emptied of their superfluous contents before the end of the fourth week. I never before witnessed so large an accumulation of feces, nor did I think it possible that, in the human subject, the bowels could be made to contain such an enormous quantity of matter as was voided from this patient during a period when no

solid food whatever was taken in, nor anything imbibed that could possibly have increased the mass already collected.

The patient is now (August 10th) perfectly recovered, and able to discharge her ordinary duties, and to walk about with comfort, when the bladder is kept within the pelvis. This is effectually done by aid of a kind of pessary formed of a small bladder, attached by its mouth to the end of a tube, whose other extremity is provided with a valve, to prevent escape of air from within. This pessary is inflated while within the vagina (the prolapsus having been previously reduced), by means of a syringe; and a T-bandage maintains it in its situation.

The uterus remains in the hollow of the sacrum, every justifiable means having been used to effect its reduction without success. The following is a brief history of the patient's illness previous to my attendance:—

About four years ago, being three or four months pregnant of her first child, she was suddenly seized, while walking in the street, with severe pain of the back and lower part of the abdomen, and an urgent desire to void the urine. Every attempt she made, however, proved ineffectual, and after several hours, the inconvenience continuing to increase, the aid of a surgeon was obtained, who relieved her with the catheter. It was found necessary to repeat the operation during five or six days, after which the patient recovered. She was delivered about five months after this of a full-grown child, who is now living. Three or four months afterwards she became aware of a descent of the womb, for which no surgical measures were adopted. About twelve months after the above-named confinement, being near the end of the third month of her second pregnancy, she experienced a recurrence of symptoms similar to those just mentioned, namely, partial suppression of urine, sometimes micturition, pain of the back, &c. These continued six or seven days,

when uterine hæmorrhage came on, accompanied by labour pains; and she was delivered of a fœtus about three months grown. Seven months later she had another miscarriage under precisely similar circumstances, and, as near as could be ascertained, at the same period of utero-gestation. A third

miscarriage took place nine months after the last, attended by the same train of symptoms, at the same period of utero-gestation, and with exactly similar results. In each of these cases the invasion of the symptoms was not sudden, as in the first instance—the one, namely, which terminated successfully for both mother and child. Their approach was gradual, under the form of what is commonly called an attack of gravel. At the onset a slight uneasiness in making water was felt, with aching across the lower part of the abdomen and hips, and pain in the back. These symptoms increased day by day; the difficulty assumed the form of micturition, which occasionally merged in total suppression of urine. After continuing for a period of from six to ten days, hæmorrhage and expulsive pains came on, and the birth of the ovum was the result. In all these instances the patient was particularly sensible of the womb remaining, after the expulsion of its contents, in a wrong position; it never returned to its "proper place." Since the last miscarriage, which occurred in the spring of 1843, she has menstruated regularly every month without an exception, the discharge continuing at each period for five or six days, and being more copious, as she thought, than it ought to have been.

At the end of February 1844, another and very severe attack of pain in the back, and around the lower part of the person, came on, accompanied by total suppression of urine. These symptoms appeared to be owing to an alteration in the situation of the womb, which, during her ordinary avocations about the house, had suddenly descended lower than usual. Her medical attendant, who relieved her with the catheter, and had occasion to see her for several days, informed her she was pregnant; this, however, she maintained could not be the case, as menstruation had ceased only a few days previously. She continued to be troubled in this manner, with only temporary relief, sometimes by means of the catheter, and occasionally by the aid of medicine, until she came under my care on the 26th of May.

It was stated above, that the patient first experienced inconvenience from what she denominates a bearing down, three or four months after her first

confinement; the womb at that period coming down beyond the external parts, and disabling her from the performance of her ordinary duties. It is probable, however, that the bearing down here spoken of consisted principally of the bladder, with only slight displacement of the womb, as she says the substance was very like what existed for a short time before labour, and which had to be returned before delivery could be effected. Since her first miscarriage, she has often tried, from professional advice, to wear a pessary, but could never bear the presence of one of any kind longer than half an hour or an hour at a time; and during the last several months she has not been able to bear the introduction of one at all, even of the softest kind and smallest dimensions, on account of the pain produced by it.

Cases like the foregoing are, I think, of rare occurrence; certainly but very few of the kind have hitherto been recorded. That its real nature, for a time, should have escaped discovery, will, I apprehend, excite no surprise, as the opening leading to the uterus was, in all its characters, so similar to the *os tinæ*, and the general appearance of the parts altogether so like an ordinary prolapsus uteri, that an idea of its being anything else was never entertained. The anatomical relations of the parts, too, seemed to preclude the possibility of descent of the bladder and vagina to such an extent, without being accompanied by the uterus; and this opinion is borne out by the fact, now sufficiently clear, that the attachment naturally existing between the external or cellular surface of the vaginal membrane and cervix uteri has been broken down; indeed, under no other circumstances could the parts have assumed the aspect described, without bringing down the lower part of the uterus at the same time. The tenesmus continuing almost unrelieved, and the prolapsed parts immoveable, even after the bowels had been so copiously evacuated; the irritation produced by the operation of administering the enemata—not merely by the introduction of the tube, but also by the presence of the liquid within the bowel, and the smallness of the quantity which could be made to pass at a time; the excruciating pain continuing

about the sacrum and hips, being the result, as I supposed, of pressure upon the sacral nerves; and, above all, the persistent state of the tumefaction in the hollow of the sacrum;—these circumstances suggested the existence of other causes, besides those which had been originally assigned, for the continuance of the disturbance in so aggravated a form.

From the extent to which the catheter would pass into the uterus, this organ, as was before stated, appeared to be considerably elongated. This, however, was not really the case, as the material extruded from the vagina was clearly no part of the uterus, but only the lining membrane of the vagina, of a reflexion of which the orifice, and the tube leading to the uterus, were formed. This is proved beyond doubt by the following evidence:—

1. On examining per vaginam below the prolapsus, the outlines and situation of the uterus can be clearly defined; its broad part below lying across the sacrum; its mouth upwards, behind the symphysis pubis, where the peculiar firm feel characteristic of the uterine texture ceases; and the continuation of the passage from this point externally is much softer and altogether different.

2. The finger can pass readily to the extent of at least an inch and a half along this membranous tube, until arrested by a firmer substance, presenting a more constricted opening, of a fissured shape, whose aspect is upward and slightly forward: this is the true *os tinæ*.

3. On introducing the catheter into the urethra, which is not more than half an inch in length at most, it will pass freely in a downward and forward direction, external to the pelvis, till its point arrives behind the fold of membrane forming the margin of what appeared to be the *os uteri*, and can be felt on the finger, when within the tube, as far as the *os tinæ*.

4. Reducing the prolapsus, and passing the vaginal membrane as far back as can be done, the orifice becomes situated in an upward direction against the fundus of the bladder; and the cervix and whole body of the uterus lying in the hollow of the sacrum can be clearly defined through this membrane.

The accumulation *a tergo* had brought

the uterus as far down as the deep pelvic fascia would allow, as this membrane was tensely stretched from one side of the pelvis to the other. It is now considerably higher, however; but, as was before stated, cannot be raised out of the hollow of the sacrum.

In regard to the length of time this state of parts has existed, it will probably be difficult to determine. It may be of recent date, or it may have existed two or three years. The uterus in its healthy unimpregnated condition has naturally, in its descent, a tendency to follow the course of the vagina; the fundus uteri, owing to its connection with the broad suspensory membrane, being always uppermost. I can conceive but one way in which retroversion could take place under these circumstances; namely, a mass of hard feces accumulated in the sigmoid division of the colon, in its descent towards the rectum, might impinge upon the uterus, and force it into the hollow of the sacrum. The more probable inference, however, is, that the displacement has existed, partially at least, ever since the patient's last miscarriage in March 1843, if not from a much earlier date. Two reasons appear in support of this supposition: 1st, her inability to wear a pessary, even of very small dimensions, or of whatever substance made, on account of the pain it occasioned along the sacrum, in the groins, and about the hips; 2d, a similar kind of suffering induced in the same parts, and quite unlike anything she used formerly to experience, during coition. To which may be added her repeated miscarriages, the peculiar symptoms accompanying each of them, the period of gestation at which they occurred, and the patient's statement that the womb never afterwards returned to its proper place.

Whichever way occasioned, however, there is little doubt that its pressure upon the rectum, acting as a constant mechanical impediment to the functional efforts of this organ, was the principal cause, originally, of all the troubles that have been enumerated. The immediate effect would be, imperfect evacuation and consequent retention of feces, which, continuing for a length of time, would have a tendency to induce an irritable state of the mucous membrane of the lower bowels,

which might result in inflammation and all its attendant evils; for feculent matter, long retained within the bowels, loses its liquid part by absorption, gradually becomes less capable of being acted upon by the mucous products, and soon acquires all the properties of a foreign irritant body; disordering the action of the mucous surfaces, changing the nature of their secretions, and sometimes producing temporary local suspension of their functions. The accumulation having become considerable, its constant action would be to push down the uterus (supposed already to be retroverted), and fix its fundus more firmly in its malposition, increasing at the same time the pressure of its mouth against the urethra. To this would succeed suppression of urine; and, as the bladder became distended, its ascent out of the pelvis would be prevented by the loaded colon, and prolapsus or rupture would be inevitable.

Another circumstance may be cited as favouring, and, indeed, as being every way sufficient in itself to effect the prolapsus of the bladder. It must be remembered, that the disposition to temporary increase of substance, and capability of distension, communicated to all the parts concerned in the process of utero-gestation during the growth of the foetus in utero, would be altogether wanting in the present case; on which account the reflexion of peritoneum prolonged from the abdominal parietes to the bladder, and thence to the uterus, being brought down in such a manner by this latter organ as to confine the bladder behind and below the pubis, would, by its unyielding tension, effectually oppose the ascent of this viscus out of the pelvis, and give it a constant tendency to escape per vaginam.

ANALYSES AND NOTICES OF BOOKS.

"L'auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Researches on Phthisis. By P. C. A. LOUIS, M.D. 2d Edition. Translated by WALTER HAYLE WALSH, M.D. London: printed for the Sydenham Society.

We have all along been rather surprised that the Council of the Sydenham

Society should have thought it expedient to publish a translation of Louis's *Researches on Phthisis*; especially during the first year of their operations, when it was a matter of the greatest moment that a careful and judicious selection of works should be made. Not that we think for one instant that Louis' work is unworthy the consideration of the Society; we are very far from doing this, regarding it as we do as one of the most complete and masterly accounts of the disease of which it professes to treat, to be found in any language. Our reason for doubting the expediency of Louis' work finding a place in the list of the Society's publications is simply this, that a translation, and that a most excellent one, exists already, by Dr. Cowan. True it is, that Dr. Cowan's translation was made from the first edition, and this by Dr. Walshe contains the further researches of Louis incorporated into the second; still, we do not think that the additions made are of sufficient number and importance to justify the Society in presenting a totally new translation to its members, many of whom must be already in possession of Dr. Cowan's work. And in saying this we are convinced we are stating the opinion of many members of the Sydenham Society.

It must be ever borne in mind by the Council, that the object of this and similar societies is to supply to its members such works as, from their rarity or expense, it would be either difficult or inconvenient for them to procure. Now, we do not think that this new translation of Louis can be brought under either one or other of these classes. Without denying the importance of the new matter found in the second edition, especially that of the chapter on Diagnosis, certain it is that a translation already existed containing by far the greater part of the matter found in the new volume, and the price of the original work is so small, that any one wishing to make himself acquainted with Louis' further researches might purchase the book itself at a very small expense.

As we have done our best to find fault, it is but fair we should give our meed of praise where praise is due. With respect to the execution of the work, Dr. Walsh has performed his task well and ably—of this there can-

not be the slightest doubt. His style is easy and flowing, with but little of the stiffness and awkwardness exhibited by some versions; and we do not use the expression as a matter of course, when we say that his translation reads like an original work. We do not complain of the way in which it is done, but simply that it should have been done at all; we are of opinion that a new version of the book was not wanted. Nevertheless, having it on our shelf, we are pleased to have that which is in itself intrinsically so full of worth among the number of our Sydenham Society's series.

MEDICAL GAZETTE.

Friday, Sept. 13, 1844.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE MEDICAL PROFESSION BILL— No. V.

WE trust that these comments of ours on the Medical Profession Bill will not be received by any individual among our brethren as dictated by any factious spirit, or the mere love of finding fault. We are conscious of no temper of the kind. On the contrary, we perform the task that has devolved upon us in this our public capacity with reluctance, and not without distaste. "Surely," as Milton says, "to every good and peaceable man, it must in nature be a hateful thing to be the displeaser and molester of others; much better would it like him to be the messenger of gladness and contentment. But when God commands to take the trumpet and blow a dolorous or a jarring blast, it lies not in man's will what he shall say or what he shall conceal." Like the mighty spirit we have invoked, we too "with small willingness endure to interrupt the pursuit of higher hopes, to leave a calm and pleasing solitariness, fed with cheerful

and confident thoughts, to embark in a troubled sea of noises and hoarse disputes, put from beholding the bright countenance of truth in the quiet and still air of delightful studies." It is only a paramount sense of duty that compels us on the course we follow. To us it seemed that the time was ripe for doing much good in the reorganization of the medical profession—that the opportunity even presented itself for accomplishing the good; but, by some strange fatality, the ripeness of the time is like to prove mere rottenness, the opportunity to do good to be turned into the occasion of perpetrating evil. We are all bound to struggle against what we regard as an imminent misfortune; and as the light came out of darkness, so we go on with our task of showing wherein the several provisions of the New Bill appear to us defective or pernicious, with a purpose always of bringing the torch in the end which shall satisfy all how easily the profession might be harmoniously reconstituted in its several departments, without violence to any one of the long established institutions connected with its study and its practice.

The 14th clause of the proposed bill enacts, "That no person, except such graduates in medicine and such other legal practitioners as are hereinafter mentioned, shall be entitled to be registered by the Council as a Licentiate in medicine and surgery, unless he shall have attained the age of *twenty-one* years, and shall have been examined by the Colleges hereinafter named; (that is to say) if in England, examined by the Royal College of Physicians of England, assisted by the Court of Examiners of the Apothecaries' Company, and also examined by the Royal College of Surgeons in England; and if in Scotland, examined by the Royal Colleges of Physicians and Surgeons of Scotland; and if in

Ireland, examined by the Royal Colleges of Physicians and Surgeons in Ireland; and in every case shall have received letters testimonial from each of the bodies by which he shall have been examined, of his being duly qualified to practise as such licentiate."

That is to say, there shall be a certain minimum of education or term of study, and by implication of age, which shall qualify the medical student to present himself as candidate for letters testimonial of his fitness to practise as a licentiate in medicine and surgery. Furnished with these, he will register himself with the Council of Health and Education, and take his place in the world as an accredited practitioner.

The examination for this first initiatory grade is to take place, if in England, before the Royal College of Physicians, "assisted by the Court of Examiners of the Apothecaries' Company," and also before the Royal College of Surgeons; if in Scotland or Ireland, before the Royal Colleges of Physicians and Surgeons of Scotland and of Ireland respectively.

The initiatory measure we think good, IF THE EDUCATION BE PITCHED SUFFICIENTLY HIGH—all depends on this. The purpose may be, to secure a constant succession of men with the accomplishments at least of the present race of general practitioners, members of the Royal College of Surgeons and licentiates of Apothecaries' Hall; or it may be to inflict upon the public a generation of men with a legal qualification to practise medicine and surgery, with no greater amount of knowledge than the apothecary of the penultimate half century possessed, who might adventure upon phlebotomy perchance, although even that with reluctance, unless a physician were at his elbow to sanction the proceeding, and whose pride was to give a clyster adroitly, and to see that the patient took his

physic regularly. This would be a great misfortune; yet we have heard some express fears that it might be attempted. We, for our own part, have better faith, and believe that it will not. If taken, the tendency of the step would obviously be to make the consulting physician and surgeon much more indispensable than he has long been every day becoming; but as only a very small proportion of the community can command his fee, it would leave the mass at the mercy of incompetency. The rich man *might* be as well served as ever—there is the highly-educated physician or surgeon, or both, at his command; the poor man would necessarily be much worse off than he need be at present.

The education of the licentiate in medicine and surgery being regulated at least after the present standard of that of the graduate in medicine and member of the Royal College of Surgeons of any of the Scotch Colleges, or of the licentiate of the Apothecaries' Society and Royal College of Surgeons of England, the community would gain; the poor man would have a better medical attendant than he can now have in any one who is singly either a graduate of a Scotch University, a member of a Royal College of Surgeons, or a licentiate of the Apothecaries' Society. We trust that the Secretary of State for the Home Department, and the independent members of the Council of Health and Education, if it ever comes to be constituted, will look narrowly to this particular. They will have evidently a great responsibility upon their shoulders.

From the principle—the creation of a class of licentiates in medicine and surgery—let us turn to the means of testing their efficiency—the examining body or bodies; for it would seem from the wording of the 14th clause, which we have quoted, that he was to undergo

two examinations, one before the College of Physicians, "*assisted by the Court of Examiners of the Apothecaries' Company*," another before the Royal College of Surgeons of England. The two examinations before different boards appears to us a clumsy contrivance. We can see the motive of it, however; the general practitioner is so often called upon to do both physick and minor surgery, to say nothing of midwifery, which, as manual, and often requiring the use of instruments, is obviously within the domain of surgery, that he could not well be sent forth unprepared for either—rhubarb in one hand, the lancet in the other; and then as there are the Royal College of Physicians and the Royal College of Surgeons, neither of them willing to yield one jot to the other, the candidate must be referred from Pall Mall East to Lincoln's Inn Fields, or from Lincoln's Inn Fields to Pall Mall East. Why could not the respective courts, or a deputation from each, meet half way, on some neutral ground? or why might they not meet one year in Pall Mall, another in Lincoln's Inn Fields, and examine the candidates at a single sitting? This would simplify the business.

But we have not yet touched, save by a side-wind, on the elaborately ingenious element in this system of examination. We are still at liberty to pause, and bid all lovers of conundrums set to work and cudgel their brains, in order that they may read a harder riddle than any that was ever propounded in diary or annual since the world began, and so secure themselves in a distinguished immortality:—Given a body, whose existence by all well-informed men is admitted to be an anomaly, whose influential position is acknowledged to be a mistake and a mischief, what is to be done with it in order that the anomaly may cease, the mistake be remedied? This is the question. Sim-

ple people would say: "Stifle the body, stop its breath; being dead, it will no longer be in the way." But there are certain objections to this short method. Even as man and other less noble animals breathe by two nostrils, so does the body in question exist by two spiracles, one commercial, old, useful perchance, and formerly the only vent; another, scientific, of recent formation, now become superfluous, prejudicial. And here simplicity steps in again, and says: "Stop up this needless blow-hole, then." But ingenuity says: "No, we shall not do that;" and we defy the most consummate interpreter of dreams and resolver of riddles, from the time of Samson and Joseph downwards, to guess what it is proposed to do with this superfluous, this useless, this pernicious body, for so it is regarded by implication through the whole of the Bill! The body is to have no say in, or connection with, matters medical, save and except to ASSIST THE ROYAL COLLEGE OF PHYSICIANS OF LONDON, IN ITS EXAMINATION OF CANDIDATES FOR THE LICENSE TO PRACTISE GENERALLY! Poor Royal College of Physicians! what have you done to deserve this? Ashes of Harvey and of Hunter, of Sydenham and of Willis, of Freind and of Mead, of Heberden and of Baillie, will ye lie still at this? Are your successors so degenerate that they require assistance in their examinations? Your old place of meeting is turned into a shambles; in the halls where subjects of high import in human anatomy and physiology were once discussed, carcases of sheep and of oxen, of calves and of swine, now hang suspended; where mind once held high festivals, carnivorous man now prowls with wolfish eyes and ravenous maw for prey! But this profanation is nothing; it is offered but to the senseless stones, Not so the contemplated indignity. Of course the President and Censors, and

Fellows of the Royal College of Physicians, are presumed to require assistance. They do not consist of a Paris, a Bright, a Chambers, a Copland, a Holland, a Seymour, a Watson, and many more besides; these men have no knowledge of medicines or their uses, or the art and mystery of prescribing them! They are to be assisted by the Court of Examiners of the Apothecaries' Company!

But to be serious, and the subject is abundantly so in fact, this association of the Court of Examiners of the Apothecaries' Society with the College of Physicians in the important trust of examiners is plainly a sop for the Worshipful Company for the abrogation of its privileges; for its extinction as a body having power over the study and practice of medicine. We cannot think it a happy suggestion. It is assistance forced on parties who do not want it, and who, we presume, when consulted, will certainly say as much.

It is dictated, as we conceive, by a misapprehension of the feelings both of the Court of Examiners of the Apothecaries' Society themselves, and of the profession at large. Who has ever held it an honour to belong to the Worshipful Company, or Society, of Apothecaries? Who has ever been sedulous to parade his L.A.S.? Who has not felt it rather as an infliction, as a quasi degradation, that he must needs associate himself with the packages, and jars, and gallipots, of the practice of medicine? At this time, indeed, at recent meetings of the general practitioners, we have seen and heard a good deal in commendation of the way in which the Worshipful Society of Apothecaries have discharged their duties, and of the advantages that must accrue to the public and the profession from the integrity of that Society with its present privileges and immunities; but this has been a mere party cry, and

was forced *ab imo pectore* of the general practitioner, when he saw himself cast off by the College of Surgeons, upon which his hopes had still rested, with which he had still held it distinction to have his name connected. The Court of Examiners of Apothecaries' Company are almost to a man members of the Royal College of Surgeons; one of them has just been drafted into the list of Fellows, and one is a member of the College of Physicians. The general practitioner of this country is, in fact, a Licentiate of Apothecaries' Company *upon compulsion*; he is a member of the College of Surgeons, and frequently of the College of Physicians, *by choice*. The College of Surgeons had but to have opened its arms to him, and given him a voice in the administration of its affairs, to have had him repudiating all connection with the lower grade of the apothecary. The way laid open to the general practitioner to achieve the distinction of being chosen an examiner in virtue of his rank as Member of the College of Surgeons or College of Physicians, it would become unnecessary to consider him in his capacity of Associate or Licentiate of the Trading Company. The practice of the vast majority of the general practitioners of this country is much rather that of the physician than the surgeon. Successful in life, and aiming at a higher position, he always associates himself with the College of Physicians, never with the College of Surgeons; and we have heard a shrewd man suggest, that now might be the time for the College of Physicians to recover its influence as the oldest and most natural head of the medical profession, to attach those to itself who of right belong to it, and ought never to have been separated from it. Let the practitioner of medicine, the professional man, be considered in his connection with the College of Phy-

sicians or of Surgeons, and all care for him as linked with the society of lower grade may be abandoned, and the College of Physicians spared, what it must surely feel as an indignity, the association in its highest functions with the apothecary, the man to whom it has hitherto been accustomed to dictate.

MOVEMENT IN THE PROFESSION.

SINCE our last, we have only notice of two additional meetings of members of the medical profession, to consider the provisions of Sir J. Graham's Medical Bill; but they are of high character, and well calculated to show the views and feelings of the profession on the measure. In the metropolis, the men of highest name and likelihood are mostly connected with the College of Physicians or College of Surgeons, even in the grade of Fellows; and the tone of London society of the best kind is essentially *apathic*—it is ill-breeding to show anything like excitement or feeling; he who did so would lose caste. Hence the apparent or public and implied indifference of the best men in the profession to the new Bill. The silence of these parties, however, must by no means be construed into approval; we never hear the Bill approved of; we never hear it spoken of in other terms than those of disapprobation. The general practitioners, too, seem to think that *their* interests are peculiarly compromised by the contemplated measure; they are alarmed, and sound the tocsin, mixing up care for themselves in very large proportion with their care for the public; they do not escape the suspicion even of inclining to do their own work under cover of merely pretended solicitude for the public. There is no profession of which so much jealousy is shown as of that of medicine: our work is so essentially bound up with charity,

which is a universal dispenser, never a receiver, of favours, that it seems as if all should be done without fee or reward. Even as common humanity, without ulterior consideration, leads us to assist him who falls accidentally in the street, so does the community feel at heart that prostrated by sickness it has a claim upon our sympathy and attention. And so in fact it has; and what is more, the claim is conceded. There are more debts incurred for medical attendance, perhaps, than for any thing else; there are certainly more bad debts on this than on any other score; yet are there probably not a dozen suits in the course of a year over the face of England, Scotland, and Ireland, at the instance of medical men, for the recovery of their just dues. We are not pleased, therefore, to see our brethren at this crisis urging too eagerly considerations that are merely personal to them; showing themselves in a selfish light, in which they do not stand habitually and in fact. Our readers know that we have still insisted on *protection to the community alone*; protection to the profession follows, if this be secured; protection to the community may be conceded; to the medical profession, as such, it never will be granted,—the spirit of the times is against it; we would not have it asked. Let our considerate readers lay this to heart. The provincial meetings on the whole have a decidedly higher tone than those that have taken place in the metropolis; probably because there are not in the provinces peculiar considerations splitting up the profession into segments, and cutting off the head from the trunk, the men who by superior acquirements, longer years devoted to study, and higher standing, are fitted to act as leaders. Nevertheless, we have to regret a somewhat too conspicuous and unfeeling mixture of the protection to the profession in these provincial meetings also. We would fain

hope to see this brought less prominently forward for the future.

The meetings alluded to above took place on the 7th and 9th inst. at Queen's College, Birmingham, Dr. John Birt Davies in the Chair, and at the General Infirmary, Bedford, Isaac Hurst, Esq. in the Chair. At the Birmingham meeting, it was resolved unanimously—

“That a Society to be called the Birmingham and Midland Districts Medical and Surgical Association be now formed, to take into consideration the provisions of Sir James Graham's Bill, and that a provisional Council be formed for the purpose of drawing up Rules and Regulations for the Members of the Association, with a view to protect the Public, and at the same time to promote the efficiency of the Medical Profession, by elevating the standard of its character and preserving its interests, and that the Council be requested to report thereon to the members at an early meeting.”

At the Bedford meeting more was done. Resolutions were passed to the effect—

“That an association be formed for the purpose of watching the progress of the Bill, and taking any steps that may be necessary to oppose the objectionable clauses; that the members of the profession, residing in the county and neighbourhood, be invited to enrol themselves as members of such association, and that a committee be appointed to transact such business as may arise in carrying out the objects of the association.

“That this meeting views with unfeigned concern the admission by Sir James Graham, in his place in Parliament, of his inability to grapple with the crying evil of quackery, an evil admitted in all ages, and involving, as it does, the life and health of every subject in the realm, and therefore possessing a paramount claim upon the attention of the legislature. That other governments have not considered the evil to be so insuperable, and that the success of their efforts to suppress it, and to protect the lives of their subjects, prove that much may be done by legislation to diminish, if not to extinguish the evil altogether.

"That the profession do not expect nor require any exclusive rights or privileges, but that, considering the inability of the public to judge of medical skill, it ought to be protected from the ignorance of pretenders, and that the present medical practitioners having been required to make themselves acquainted with their profession at a great expense, it is the opinion of this meeting that all persons practising medicine or surgery should also be duly qualified for that purpose."

There are several other resolutions objecting to, and one approving of, several other provisions of the Bill, concluding with the hope "that Sir James Graham will not be deterred by the opposition which some parts of the Bill have called forth, from reconsidering the subject, and from granting such protection as may guard the public from imposition, and the profession from the inroads of the uneducated and unqualified.

REPORTS OF CASES
OCCURRING AT
THE WESTMINSTER HOSPITAL.
WITH REMARKS,

By B. PHILLIPS, Esq. F.R.S.

*Injury to the Scrotum followed by
Sloughing.*

JOHN HARPER, æt. 32, brewer's drayman, admitted into Henry Hoare's Ward, June 3, 1844, under Mr. White, having received a blow on the scrotum. He states that he had suffered from hydrocele for several months, which had been gradually increasing in size, but he had not used any means for its relief. He was in a state of considerable irritation, with small pulse, when admitted, and, although brought to the hospital immediately after the receipt of the injury, the scrotum was greatly swollen. He was placed in bed, and a small quantity of stimulus given him, and warm fomentations were applied to the scrotum.

June 4th.—Complains of great pain from the distension of the injured parts; not slept during the night.

Hirudines xvij. to be applied to the scrotum, and to take the following mixture:—

℞ Liq. Am. Acet. ʒj.; Tr. Opii, ℥xx.; Mist. Camph. ʒvj. Ft. Mist. ʒj. 4tis horis.

5th.—Slept for a short time during the night, but still in great pain; bowels confined; the leeches bled a good deal, and the scrotum is not so vividly red as it was; pulse 118, small.

℞ Haust. Aper. statim, and poppy fomentation to the scrotum.

6th.—Bowels freely moved; the constitution is beginning to suffer from the local injury; a considerable degree of irritative fever is set up, and the pulse is very quick, and occasionally intermittent; the scrotum is excessively tender, so much so, that he cannot bear the slightest touch.

℞ Hyd. Chloridi, gr. ij.; Opii, gr. iiss. Ft. Pil. statim sumend.

℞ Mist. Morphæ, ℥xx.; Aq. Distil. ʒj. Ft. haust. hora somni cap. Porter, Oj.

7th.—No better; the surface of the scrotum is becoming of a brownish tinge, and the constitutional irritation is kept up.

Ordered to apply a yeast poultice, and take during the day Porter and Decoct. Cinchona, ʒiiss. 4tis horis.

8th.—Has been delirious during the night, wanting to get out of bed; he is very sick; sloughing has commenced in the lower part of the scrotum, and the upper looks as though it will soon be in the same state. Several incisions were made through the whole extent of the scrotum, which relieved the tension.

℞ Vin. Rubri, ʒj. 3tis horis sumend.

9th.—The sloughing is spreading very rapidly; he has constant hiccough, with vomiting.

Cont. Med. et Vin.

10th.—The whole of the scrotum is now gangrenous, and the man lies comatose, and apparently moribund, but the pulse is fuller and better than yesterday, being down to 98.

Ordered to have a large blister at the back of the neck, and a Turpentine Enema. Cont. Vin.

11th.—He is rather more sensible to-day; blister rose well; the sloughing has stopped, having destroyed the greater part of the scrotum.

Rept. Vin., and Brandy, ʒiv.; Beef Tea.

12th.—Better; slept well; bowels rather relaxed.

14th.—Improving; the process of separation has commenced.

℞ Quinin. Disulph. gr. iiss.; Tr. Card. Comp. ʒj.; Aquæ, ʒj. Ft. haust. ter die sumend. Full diet, Porter Oj. daily.

20th.—The greater portion of the slough has come away, leaving the testicle exposed on the left side; going on well; appetite good; sleeps well.

26th.—Doing well.

July 4th.—Going on well; the wound gradually closing over the testicle, but the hydrocele on the right side remains as before the injury.

28th.—The man has been gradually gaining strength, and the wound healing, and will leave the hospital in a few days, it being determined to leave the hydrocele alone for a short time.

REMARKS.—The preceding case is one of a class which in their treatment require particular attention to one point, viz. keeping up the strength. The patient was accustomed to drink fifteen or sixteen pints of beer daily, and the want of that stimulus even for forty-eight hours materially aggravated the mischief. The blow had not occasioned any apparent injury to the testicle, neither had it produced excessive pain, but there was reason to think that it had caused the rupture of the tunica vaginalis, and that the condition of the scrotum was mainly owing to the escape of the hydrocele fluid into the cellular tissue of the scrotum. Supposing that to be a correct view of the case, we had expected the hydrocele to be cured; but it was soon evident that the probably ruptured sac, and the great mischief set up around it, were not likely to effect a cure. In some cases of dropsy a cure has followed the rupture of the sac—in many cases even needle punctures will serve to empty the sac of the hydrocele—but in this case neither of these results was obtained. At the time of his discharge, Mr. Phillips thought it prudent to let the hydrocele remain for a few weeks, lest, in the event of its being injected, the inflammatory action then set up might provoke further mischief in the scrotum.

ACUTE GLANDERS FOLLOWING A BITE BY A HORSE.

By M. LANDOUZY.

A VINE-GROWER, fifteen days after buying a horse in July 1843, perceived that it was labouring under glanders. The disease was communicated to an ass living in the same stable. In order to make the horse take the drinks, the proprietor used to open his jaws with the help of a rope. One day the rope broke, and the jaws closing suddenly, he received a bite on his cheek. On the 20th of December, being two days after this, symptoms of acute glanders manifested themselves. A pustular eruption, abundant discharge from the nares, dyspnoea, diminution of the respiratory murmur, abscesses, &c.; and in addition to these

symptoms, there appeared one that has not yet been described—opacity of the cornea.

The man died on the 2d of January. At the autopsy an abundant eruption was found on the thorax and the abdomen: the bronchi were covered by a military eruption; the lung was filled with abscesses; the liver and spleen were evidently increased in size; in the intestines there was a military eruption above and below the cæcum, and in the cæcum seven ulcerations, a lesion that has not yet been mentioned. The principal features of interest which the case presents are, its inoculation by a bite, the opacity of the cornea, and the ulcerations of the cæcum.

M. Barthelemy remarked, that the horse had been five months ill, and that, consequently, as the case was one of acute glanders, communicated by a bite from an animal chronically diseased, the distinction which some persons had attempted to establish between acute and chronic glanders was not warranted."—*Veterinarian*, Sept. 1844.

LECTURES
ON THE
NATURE AND TREATMENT OF
DEFORMITIES,
*Delivered at the Orthopædic Institution,
Bloomsbury Square.*

By R. W. TAMPLIN, F.R.C.S.E.
Surgeon to the Institution.

TALIPES VARUS.

IN my last lecture I was engaged in pointing out the characters of talipes equinus, and showed that the deformity consisted essentially in a contraction of the gastrocnemius muscle, that it arose from local as well as from general causes, and that in the latter case paralysis would be found very frequently co-existing; that in the local form, although paralysis of the flexors might not be present, yet that the resistance to the reposition of the foot was more obstinate, and the restoration of the extremity to its natural state more tedious, difficult, and painful; that occasionally, during the progress of flexion, the foot might deviate to one or the other side from a contraction of the peronei, or of the anterior or posterior tibial tendons, which contraction appears to be the result of habitual position, rather than of any disturbance in the nerves supplying the muscles*.

* I would here observe, that I have no belief in the "inherent irritability" of muscular fibre; nor do I consider the contraction of muscle after death any evidence of such inherent irritability. Doubtless the muscle is freely supplied with nerves, and those nerves divide and re-divide and anastomose freely in every direction, but it is the irritation of these muscular nervous fibres, and that only, in my opinion, which occasions the contraction of the muscle. But this is not, to my mind, to be considered as muscular irritability, but an irritability of the nerves ramifying in and supplying the muscle; this irritability, as a natural consequence, affecting the muscle itself. It behoves us to be cautious

I stated that the temperature of the entire limb during the treatment is occasionally much reduced, so that it becomes very necessary to pay attention to this, as, by neglecting the temperature, comparatively slight pressure will often produce a slough, and then a wound, tedious and troublesome to heal, and during the open state of which it will be necessary to suspend the treatment. You can, however, maintain the foot in the position to which it has been brought, by the continued application of a splint well padded: although you cannot advance, you may at all events prevent any relapse. As soon as the wound is healed you will, of course, recommence extension. In cases where I have had to encounter these sloughs, I have found the best method of treatment to be, to support the foot entirely by means of strapping: you thus prevent the weakened capillaries from becoming over distended; and if the vitality is not completely gone, the part will recover itself. And even should the vitality be destroyed, the threatened slough will frequently dry up and terminate without any open wound. An instance illustrating this occurred some time since in a case of paralytic contraction of the foot and knee of a girl a patient in the institution. After some days' treatment, during which time the patient did not complain of the smallest amount of pain, I noticed an ecchymosis on the great toe; and on removing the instrument, found a black spot on the instep the size of a five-shilling piece. I immediately strapped the foot from the toes to the ankle-joint, and supported the entire limb with a flannel bandage. No pain or inconvenience followed, and for fourteen days it was allowed to remain. From some cause which it is unnecessary to mention, the strapping was removed; the black colour,

in assenting to this or that doctrine without conclusive proof, as by so doing we may mislead ourselves, and place an obstacle in the way of treatment from a wrong impression as to the cause of the disease.

it was found, had entirely disappeared, and the part which was threatened with sphacelus presented a darkish red gelatinous appearance, with vessels ramifying through it, the surface being continuous with the healthy structure. Flour was now applied to the injured surface, and the extremity was covered with flannel bandages, the strapping being omitted. In the course of three or four hours the foot and leg became immensely swollen, red, and painful, having the acute erysipelatous appearance. The removal of the strapping had completely interrupted the restorative process, by withdrawing the uniform support. The capillaries, already weakened by the paralytic condition of the limb, immediately gave way, and became unable to carry on the circulation, from their dilated and over-distended condition, so that a complete stricture, like that which would have followed the application of a ligature, was formed entirely round the injured part, whereby its vitality was entirely destroyed: the part reassumed its black appearance, the slow process of separation followed, and a large wound was the result, which occupied some weeks in healing. The case, however, was very instructive, as it clearly illustrated the weakened condition of the capillary vessels, and the impossibility of the circulation when at all excited being carried on in parts having the low state of vitality which is frequently found to exist along with paralytic affections.

The consequences of removing the support afforded by the strapping in this case was a sort of self-strangulation of the part: the weakened and dilated capillaries could not withstand the full force of the heart; they became over distended, the blood stagnated in their channels, and the part died from want of a due supply of the vivifying fluid, the blood. I would advise, therefore, that in all cases of this kind recourse should be had to the uniform and constant support afforded by strapping. A bandage, however carefully applied, will not effectually render the absolutely necessary, uniform, and constant support which is attained by strapping. It is well to apply a bandage over the strapping, as it serves to preserve the temperature of the limb. I directed your observation to the necessity of applying a boot and suitable support as soon as the foot was sufficiently flexed, which support must be continued until the weakened muscles have regained sufficient strength to prevent the chance of a relapse. The boot will frequently be necessary for years, as in the case related by D. L. : it is a great comfort to the patient, and does not interfere with the motions of the joint, nor will the slightest *ulterior inconvenience* arise from its use.

I now proceed to consider particularly that species of deformity called *talipes varus*

By *talipes varus* is understood that kind of deformity which consists, 1stly, in the elevation of the heel, from contraction of the *gastrocnemius*; 2dly, in the adduction and semirotation of the anterior portion of the foot by the contraction of the anterior and posterior tibial tendons; 3dly, in a shortened condition of the sole, occasioned, 1stly, by the adduction of the foot; 2dly, by the contraction of the plantar fascia, muscles, and ligaments of the sole. In adults you will find also a great increase of the lateral or transverse arch of the foot, which has been brought on by the constant pressure of the weight of the body, in walking on the outer and dorsal surface of the fifth metatarsal bone, which thus becomes approximated to the metatarsal bone of the great toe (vide fig. 2). You will then find the *os scaphoides* approximated to the internal malleolus, and separated from the external anterior side of the surface of the astragalus. The *os cuboides*, again, is separated on its outer aspect from the *os calcis*, and closely pressed on its internal side to the inner edge of the articular surface of the *os calcis*, and also of the external portion of the anterior articular surface of the astragalus; this being the principal change caused by the adduction of the foot. We have also the almost perpendicular position of the *os calcis*, as in the *talipes equinus*, and the oblique position of the astragalus. The fourth and fifth metatarsal bones will also be found separated slightly from the outer side of their articulation with the *os cuboides*, but the principal change of position is between the astragalus and *os scaphoides*, and the *os calcis* and cuboid bone. The anterior portion of the foot remains very nearly in its natural relative position, at least so far as the position of the bones is concerned. The calcaneo-cuboid ligament becomes stretched on its outer portion, and contracted on the inner. The calcaneo-scaphoid ligament is also stretched. The superior and external calcaneo-cuboid will likewise be found elongated. The internal lateral or deltoid ligament is contracted. Of course the other ligaments are all more or less changed from their natural length and position, but those particularly mentioned are the most important. In the increase of the transverse arch of the foot in the adult deformity, you will find the transverse bands contracted, and offering a powerful resistance. The muscles which are contracted, and the immediate cause of the malposition, are, 1st, the *gastrocnemius*, 2d, the adductors direct, viz. the anterior and posterior tibial, the extensor and flexor of the great toe, as well as the extensor and flexor communis indirectly. The peronei are elongated, or rather kept upon the stretch. The contraction of the ligaments does not apply to infants, but becomes so

FIG. 1.

from position. This deformity is both congenital and non-congenital; but in a large proportion it is the most common form of congenital deformity. In the congenital you will find no paralysis; in the non-congenital, paralysis of one or more muscles will very generally be found; and this applies to almost every non-congenital deformity. I have never seen a congenital paralytic affection of any of the muscles in any deformity, nor do I believe that it exists. In the infant you will find the size of the affected limb correspond with that of the well-formed and perfectly proportioned one; but of course, as the child grows, the foot remaining in its false position, and the play of the

muscles in that foot being most limited, the muscles, as a natural consequence, become developed but very slowly; and as the child continues to grow, the limb presents the appearance of an atrophied extremity, the natural outline of well-developed muscles being entirely absent; and yet all this arises entirely from want of use, as no paralysis exists, nor any loss of the voluntary power. The temperature of the limb is natural, but the foot does not resist the effect of cold so well as the naturally-placed foot; but this, I imagine, is entirely owing to its passive condition, and not from any diminished nervous power, or loss of its proper tone; as it is not merely the motion of the ankle-joint that is limited, the muscles which move it are of necessity scarcely if at all able to perform their functions.

There will be found in the adult, and at all periods from the time the patient begins to walk, more or less thickening and induration of the cellular tissue, corresponding to the point or points of pressure, which increases the deformed appearance. In the infant you have the round and natural appearance without any addition to the deformity occasioned by contraction of muscles; and upon examining it you find the anterior portion of the foot entirely perfect (vide fig. 4), and that with some little force, oftentimes, indeed, without any, you will be enabled, by *adduction* simply, to place the foot in a straight line with the tibia and fibula, there being no increase of the transverse arch. Occasionally, but very rarely, I have found the plantar fascia decidedly contracted; and this contraction must have existed some time previous to birth, as the skin will be

it was found, had entirely disappeared, and the part which was threatened with sphacelus presented a darkish red gelatinous appearance, with vessels ramifying through it, the surface being continuous with the healthy structure. Occasionally, but very rarely, I have found the plantar fascia decidedly contracted; and this contraction must have existed some time previous to birth, as the skin will be

found drawn in: this is, however, the exception, not the rule.

The causes of talipes varus (congenital) are supposed by some to arise from mental impressions, or some sudden fright occurring during pregnancy; others think it proceeds from irritation or disease of the brain, its membranes, or spinal chord. Others have supposed that *position in utero* has produced it. It is true, the mother will, in the majority of cases, assign it to some impression or fright; but this appears to me exceedingly questionable and doubtful, as there is scarcely a pregnant woman who during pregnancy, at one time or another, does not receive some fright, and the proportion of deformities as compared with the number born is very small. Again, very frequently the mother will tell you she can imagine nothing nor recollect anything which could have produced the deformity. On the books of this institution many cases of this kind will be found; and then nothing is more common than for patients in general illness being perfectly satisfied that they are aware of the cause of their illness, however wide they may be from the actual fact; so natural is it for the timid to endeavour thus to satisfy themselves. We cannot therefore place much, if any, dependence on these theories. With regard to the brain or nerves of the fetus being diseased, and thus occasioning it, on this I am also sceptical, for there is not a shadow of proof that such has ever been the case. In the first place, the contracted muscles are not in a state of spasm, neither are those on the outside of the foot paralysed or deficient in any respect, more than this, that the adductors have the preponderance, and the abductors have not the power to overcome the adductors; but place the foot in its proper position and you will find that the peronei will hold it out, and during volition evert the foot. The muscles producing the deformity are certainly contracted, but there is no evidence of any irregular action. The patient can at all times exercise the steady well-directed action of the muscles, even in varus, so far as the deformity will allow; and the foot remains perfectly quiet in the absence of the voluntary effort. Direct a boy or adult afflicted with varus to draw up his foot (which we frequently do in order to facilitate the operation), and you will find it is done instantly; direct him also to evert it, and place your hand on the peronei, and you will find them instantly contract, although he may not possess, and does not possess, the power of everting the foot in the least, because of the confirmed malposition. Again, it is a singular fact that at whatever age the patient may be suffering from talipes varus, neither the *contracted muscles nor those extended, and which have been extended for years, suffer*

in the slightest degree beyond their want of development consequent upon their want of exercise. This would not be the case if there was any disease of the nerves or their centres. Again, take the non-congenital deformity, when the disease or irritation of the brain or spinal chord has been the cause producing paralysis, do we find that we can control or remove the loss of power? Certainly not; it continues; and at present we know of no remedy for complete paralysis, the muscle itself wasting and degenerating into a sort of fatty condition. There are cases where paralysis has been the first symptom, and deformity the result; where every muscle will be found to have recovered itself, and after the restoration of the foot into its position will by exercise maintain the motions of the foot; but this is the exception, not the rule. Whereas in congenital deformity it is quite the reverse, and I have never, as I have before stated, witnessed a *congenital paralytic* condition. I cannot therefore place any faith in the opinion that the malposition arises from such a cause. Lastly, as regards the position in utero: this, I think, the most probable cause, although we can have no proof beyond the fact, that in some of the varieties of non-congenital deformity, position appears to favour contraction, and in my opinion certainly does so; even in cases, you will observe, where the muscles have possessed their power, and have been for years fulfilling their natural functions, yet from being kept in one position they became contracted in that position without any (so called) structural shortening; even the passive organs of the joints themselves become contracted from position without any change in their healthy condition, or, in my opinion, actual shortening. How much more likely should we consider it that a muscle should become fixed and contracted in the position in which it has been kept for a longer or shorter period; therefore, so far as I can judge, I certainly am inclined to regard the exciting cause of the deformity as arising from the position in utero. But we have as yet no proof of this being the fact, and I fear it is not likely we shall find indisputable evidence to establish it.

Patients afflicted with varus have not, as you must perceive, any motions available for walking, in the ankle-joint. They are, therefore, compelled to walk with a perfectly stiff limb below the knee, and the sole of the foot is turned backwards off the ground (vide fig. 2), whilst the dorsum is placed directly forwards (vide fig. 1), the inner portion being elevated, and the anterior portion, including the phalanges, metatarsus, and tarsus, being at right angles with the os calcis, astragalus, and ankle-joint (vide figs. 1 & 2); hence the peculiar appearance and hideous deformity which these unfortunate objects present in walking,

by the anterior portion of one foot being carried over the other during the act of progression, in double varus. In the majority of cases you will find double varus to exist; there are, however, a great number of cases where only one foot is affected. The pain and inconvenience experienced by the patient are frequently very great, from the constant pressure on one point, and that point being an artificial one, whereby inflammation occasionally is set up in the cushion formed by nature to protect the bones, and is followed by supuration, and a tedious wound, during the healing of which the patient is totally prevented from using the limb. Even after the wound is healed great pain and tenderness are experienced, in consequence of the pressure then becoming directed on the bones themselves: the protecting matter having suppurated, has left them, comparatively speaking, exposed. At all times a great degree of lameness and stiffness in walking is the result; and yet many walk miles during the day with comparatively little inconvenience. Cases even occur among persons who are compelled to obtain their existence by their daily labour, but most of these unfortunate creatures follow some sedentary occupation, such as that of a tailor or shoemaker; still we have had one or two instances of agricultural labourers suffering under this affliction, who have been compelled, from the nature of their occupation, to be on their legs from morning till night, and who have not been prevented from following their duties. Occasionally they suffer during the winter from the effect of cold, in the shape of chilblains, but not, I think, more than others do who are not thus afflicted (at least the congenital.) The limb below the knee will be found much wasted; but although this is the case, yet the muscles still retain their healthy character; the deformity also affects the development of the muscles of the entire extremity, as may be observed in the instances of single varus.

Congenital varus very generally exists without any additional deformity, but cases will be met with in which the knee is also contracted, and in which some irregularity also exists, such as an actual deficiency and malformation, and supernumerary toes, (vide fig. 4). In this case the child had six toes on each foot, and five fingers on each hand, but this does not appear to occur more frequently in cases of varus than it does without any malposition of the extremities. Occasionally there will be found a relaxed state of the ligaments of the knee, which admit of a sort of rotatory motion, the tibia on the femur, which gives an additional amount of severity in the appearance of the deformity, the foot appearing to be rotated more inwards. This will require attention in the after-treatment. I have seen

some few instances of incipient lateral curvature of the spine, in children afflicted with single varus, from the excessive motion kept up in the vertebral column from the lameness of one extremity. This increase of mobility between the vertebrae will be found to terminate occasionally in lateral curvature, provided the deformity is not removed, and the motions of both limbs made to correspond with each other. This applies to lameness of one or other lower extremity, from whatever cause such lameness may arise.

Cases of varus will be met with in every amount of severity, both in the infant as well as in the adult. In the former the increased severity arises from a more complete and rigid contraction of the muscles alone, whilst in the latter the rigidity will be found to exist in the muscles; and, secondly, by far the most obstinate resistance will be found in the passive attachment of the bones and joints, viz. the ligaments. In the infant, you will be enabled frequently, with but little force, to place the foot in its natural position, and it will return to its contracted state but slowly, and in some cases the foot occasionally assumes its natural position, but seems to invert itself slightly when the muscles are acting. In others a fixed contraction appears to exist, so that after you have abducted the foot it will return by an elastic impulse to its false position, but this depending on the amount of the muscular contraction. In the case I mentioned in my first lecture the contraction was complete previous to the operation, yet upon examining the tendons a linear cicatrix could be detected, and that only after maceration, and then very imperfectly. And yet the foot was held and maintained in its natural position, and the little patient up to the time of its illness could use it freely in that position.

I have never witnessed any spasm in true varus simply, nor do I think it does exist. The return of the foot to its false position after it has been forcibly held out is not the result of *spasm*, but of the return of the muscles to its contracted position which has thus been forcibly drawn out. Again, where is the evidence of spasm after the cure is effected, when the patient possesses the voluntary movements, and freely exercises them? In fact, as far as my observation goes, there is no diseased or unhealthy action of the muscles contracted. In the adult, and during the period of youth, you will also meet with the deformity in every amount of severity. In some cases a great amount of motion will be found on any attempt to abduct the foot; in others will be found the most firm and unyielding resistance, which appears to depend considerably on the health and constitution of the patient, more so than on the

found drawn in: this is, however, the exception, not the rule.

The causes of talipes varus (congenital) are supposed by some to arise from mental impressions, or some sudden fright occurring during pregnancy: others think it proceeds from irritation or disease of the brain, its membranes, or spinal chord. Others have supposed that *position in utero* has produced it. It is true, the mother will, in the majority of cases, assign it to some impression or fright: but this appears to me exceedingly questionable and doubtful, as there is scarcely a pregnant woman who during pregnancy, at one time or another, does not receive some fright, and the proportion of deformities as compared with the number born is very small. Again, very frequently the mother will tell you she can imagine nothing nor recollect anything which could have produced the deformity. On the books of this institution many cases of this kind will be found; and then nothing is more common than for patients in general illness being perfectly satisfied that they are aware of the cause of their illness, however wide they may be from the actual fact; so natural is it for the timid to endeavour thus to satisfy themselves. We cannot therefore place much, if any, dependence on these theories. With regard to the brain or nerves of the fœtus being diseased, and thus occasioning it, on this I am also sceptical, for there is not a shadow of proof that such has ever been the case. In the first place, the contracted muscles are not in a state of spasm, neither are those on the outside of the foot paralysed or deficient in any respect, more than this, that the adductors have the preponderance, and the abductors have not the power to overcome the adductors; but place the foot in its proper position and you will find that the peronei will hold it out, and during volition evert the foot. The muscles producing the deformity are certainly contracted, but there is no evidence of any irregular action. The patient can at all times exercise the steady well-directed action of the muscles, even in varus, so far as the deformity will allow; and the foot remains perfectly quiet in the absence of the voluntary effort. Direct a boy or adult afflicted with varus to draw up his foot (which we frequently do in order to facilitate the operation), and you will find it is done instantly; direct him also to evert it, and place your hand on the peronei, and you will find them instantly contract, although he may not possess, and does not possess, the power of everting the foot in the least, because of the confirmed malposition. Again, it is a singular fact that at whatever age the patient may be suffering from talipes varus, neither the contracted muscles nor those extended, and which have been extended for years, suffer

in the slightest degree beyond their want of development consequent upon their want of exercise. This would not be the case if there was any disease of the nerves or their centres. Again, take the non-congenital deformity, when the disease or irritation of the brain or spinal chord has been the cause producing paralysis, do we find that we can control or remove the loss of power? Certainly not; it continues; and at present we know of no remedy for complete paralysis, the muscle itself wasting and degenerating into a sort of fatty condition. There are cases where paralysis has been the first symptom, and deformity the result; where every muscle will be found to have recovered itself, and after the restoration of the foot into its position will by exercise maintain the motions of the foot; but this is the exception, not the rule. Whereas in congenital deformity it is quite the reverse, and I have never, as I have before stated, witnessed a *congenital paralytic* condition. I cannot therefore place any faith in the opinion that the malposition arises from such a cause. Lastly, as regards the position in utero: this, I think, the most probable cause, although we can have no proof beyond the fact, that in some of the varieties of non-congenital deformity, position appears to favour contraction, and in my opinion certainly does so; even in cases, you will observe, where the muscles have possessed their power, and have been for years fulfilling their natural functions, yet from being kept in one position they became contracted in that position without any (so called) structural shortening; even the passive organs of the joints themselves become contracted from position without any change in their healthy condition, or, in my opinion, actual shortening. How much more likely should we consider it that a muscle should become fixed and contracted in the position in which it has been kept for a longer or shorter period; therefore, so far as I can judge, I certainly am inclined to regard the exciting cause of the deformity as arising from the position in utero. But we have as yet no proof of this being the fact, and I fear it is not likely we shall find indisputable evidence to establish it.

Patients afflicted with varus have not, as you must perceive, any motions available for walking, in the ankle-joint. They are, therefore, compelled to walk with a perfectly stiff limb below the knee, and the sole of the foot is turned backwards off the ground (vide fig. 2), whilst the dorsum is placed directly forwards (vide fig. 1), the inner portion being elevated, and the anterior portion, including the phalanges, metatarsus, and tarsus, being at right angles with the os calcis, astragalus, and ankle-joint (vide figs. 1 & 2); hence the peculiar appearance and hideous deformity which these unfortunate objects present in walking,

by the anterior portion of one foot being carried over the other during the act of progression, in double varus. In the majority of cases you will find double varus to exist; there are, however, a great number of cases where only one foot is affected. The pain and inconvenience experienced by the patient are frequently very great, from the constant pressure on one point, and that point being an artificial one, whereby inflammation occasionally is set up in the cushion formed by nature to protect the bones, and is followed by suppuratation, and a tedious wound, during the healing of which the patient is totally prevented from using the limb. Even after the wound is healed great pain and tenderness are experienced, in consequence of the pressure then becoming directed on the bones themselves: the protecting matter having suppurated, has left them, comparatively speaking, exposed. At all times a great degree of lameness and stiffness in walking is the result; and yet many walk miles during the day with comparatively little inconvenience. Cases even occur among persons who are compelled to obtain their existence by their daily labour, but most of these unfortunate creatures follow some sedentary occupation, such as that of a tailor or shoemaker; still we have had one or two instances of agricultural labourers suffering under this affliction, who have been compelled, from the nature of their occupation, to be on their legs from morning till night, and who have not been prevented from following their duties. Occasionally they suffer during the winter from the effect of cold, in the shape of chilblains, but not, I think, more than others do who are not thus afflicted (at least the congenital.) The limb below the knee will be found much wasted; but although this is the case, yet the muscles still retain their healthy character; the deformity also affects the development of the muscles of the entire extremity, as may be observed in the instances of single varus.

Congenital varus very generally exists without any additional deformity, but cases will be met with in which the knee is also contracted, and in which some irregularity also exists, such as an actual deficiency and malformation, and supernumerary toes, (vide fig. 4). In this case the child had six toes on each foot, and five fingers on each hand, but this does not appear to occur more frequently in cases of varus than it does without any malposition of the extremities. Occasionally there will be found a relaxed state of the ligaments of the knee, which admit of a sort of rotatory motion, the tibia on the femur, which gives an additional amount of severity in the appearance of the deformity, the foot appearing to be *rotated more inwards*. This will require attention in the after-treatment. I have seen

some few instances of incipient lateral curvature of the spine, in children afflicted with single varus, from the excessive motion kept up in the vertebral column from the lameness of one extremity. This increase of mobility between the vertebrae will be found to terminate occasionally in lateral curvature, provided the deformity is not removed, and the motions of both limbs made to correspond with each other. This applies to lameness of one or other lower extremity, from whatever cause such lameness may arise.

Cases of varus will be met with in every amount of severity, both in the infant as well as in the adult. In the former the increased severity arises from a more complete and rigid contraction of the muscles alone, whilst in the latter the rigidity will be found to exist in the muscles; and, secondly, by far the most obstinate resistance will be found in the passive attachment of the bones and joints, viz. the ligaments. In the infant, you will be enabled frequently, with but little force, to place the foot in its natural position, and it will return to its contracted state but slowly, and in some cases the foot occasionally assumes its natural position, but seems to invert itself slightly when the muscles are acting. In others a fixed contraction appears to exist, so that after you have abducted the foot it will return by an elastic impulse to its false position, but this depending on the amount of the muscular contraction. In the case I mentioned in my first lecture the contraction was complete previous to the operation, yet upon examining the tendons a linear cicatrix could be detected, and that only after maceration, and then very imperfectly. And yet the foot was held and maintained in its natural position, and the little patient up to the time of its illness could use it freely in that position.

I have never witnessed any spasm in true varus simply, nor do I think it does exist. The return of the foot to its false position after it has been forcibly held out is not the result of *spasm*, but of the return of the muscles to its contracted position which has thus been forcibly drawn out. Again, where is the evidence of spasm after the cure is effected, when the patient possesses the voluntary movements, and freely exercises them? In fact, as far as my observation goes, there is no diseased or unhealthy action of the muscles contracted. In the adult, and during the period of youth, you will also meet with the deformity in every amount of severity. In some cases a great amount of motion will be found on any attempt to abduct the foot; in others will be found the most firm and unyielding resistance, which appears to depend considerably on the health and constitution of the patient, more so than on the

found drawn in : this is, however, the exception, not the rule.

The causes of talipes varus (congenital) are supposed by some to arise from mental impressions, or some sudden fright occurring during pregnancy ; others think it proceeds from irritation or disease of the brain, its membranes, or spinal chord. Others have supposed that *position in utero* has produced it. It is true, the mother will, in the majority of cases, assign it to some impression or fright ; but this appears to me exceedingly questionable and doubtful, as there is scarcely a pregnant woman who during pregnancy, at one time or another, does not receive some fright, and the proportion of deformities as compared with the number born is very small. We cannot therefore place much, if any, dependence on these theories. With regard to the brain or nerves of the fetus being diseased, and thus occasioning it, on this I am also sceptical, for there is not a shadow of proof that such has ever been the case. In the first place, the contracted muscles are not in a state of spasm, neither are those on the outside of the foot paralysed or deficient in any respect, more than this, that the adductors have the preponderance, and the abductors have not the power to overcome the adductors ; but place the foot in its proper position and you will find that the peronei will hold it out, and during volition evert the foot. The muscles producing the deformity are certainly contracted, but there is no evidence of any irregular action. The patient can at all times exercise the steady well-directed action of the muscles, even in varus, so far as the deformity will allow ; and the foot remains perfectly quiet in the absence of the voluntary effort. Direct a boy or adult afflicted with varus to draw up his foot (which we frequently do in order to facilitate the operation), and you will find it is done instantly ; direct him also to evert it, and place your hand on the proni, and you will find them instantly contract, although he may not possess, and does not possess, the power of everting the foot in the least, because of the confirmed malposition. Again, it is a singular fact that at whatever age the patient may be suffering from talipes varus, neither the contracted muscles nor those extended, and which have been extended for years, suffer

in the slightest degree beyond their want of development consequent upon their want of exercise. This would not be the case if there was any disease of the nerves or their centres. Again, take the non-congenital deformity, when the disease or irritation of the brain or spinal chord has been the cause producing paralysis, do we find that we can control or remove the loss of power ? Certainly not ; it continues ; and at present we know of no remedy for complete paralysis, the muscle itself wasting and degenerating into a sort of fatty condition. There are cases where paralysis has been the first symptom, and deformity the result ; where every muscle will be found to have recovered itself, and after the restoration of the foot into its position will by exercise maintain the motions of the foot ; but this is the exception, not the rule. Whereas in congenital deformity it is quite the reverse, and I have never, as I have before stated, witnessed a *congenital paralytic* condition. I cannot therefore place any faith in the opinion that the malposition arises from such a cause. Lastly, as regards the position in utero : this, I think, the most probable cause, although we can have no proof beyond the fact, that in some of the varieties of non-congenital deformity, position appears to favour contraction, and in my opinion certainly does so ; even in cases, you will observe, where the muscles have possessed their power, and have been for years fulfilling their natural functions, yet from being kept in one position they became contracted in that position without any (so called) structural shortening ; even the passive organs of the joints themselves become contracted from position without any change in their healthy condition, or, in my opinion, actual shortening. How much more likely should we consider it that a muscle should become fixed and contracted in the position in which it has been kept for a longer or shorter period ; therefore, so far as I can judge, I certainly am inclined to regard the exciting cause of the deformity as arising from the position in utero. But we have as yet no proof of this being the fact, and I fear it is not likely we shall find indisputable evidence to establish it.

Patients afflicted with varus have not, as you must perceive, any motions available for walking, in the ankle-joint. They are, therefore, compelled to walk with a perfectly stiff limb below the knee, and the sole of the foot is turned backwards off the ground (vide fig. 2), whilst the dorsum is placed directly forwards (vide fig. 1), the inner portion being elevated, and the anterior portion, including the phalanges, metatarsus, and tarsus, being at right angles with the os calcis, astragalus, and ankle-joint (vide figs. 1 & 2) ; hence the peculiar appearance and hideous deformity which these unfortunate objects present in walking.

by the anterior portion of one foot being carried over the other during the act of progression, in double varus. In the majority of cases you will find double varus to exist; there are, however, a great number of cases where only one foot is affected. The pain and inconvenience experienced by the patient are frequently very great, from the constant pressure on one point, and that point being an artificial one, whereby inflammation occasionally is set up in the cushion formed by nature to protect the bones, and is followed by supuration, and a tedious wound, during the healing of which the patient is totally prevented from using the limb. Even after the wound is healed great pain and tenderness are experienced, in consequence of the pressure then becoming directed on the bones themselves: the protecting matter having suppurated, has left them, comparatively speaking, exposed. At all times a great degree of lameness and stiffness in walking is the result; and yet many walk miles during the day with comparatively little inconvenience. Cases even occur among persons who are compelled to obtain their existence by their daily labour, but most of these unfortunate creatures follow some sedentary occupation, such as that of a tailor or shoemaker; still we have had one or two instances of agricultural labourers suffering under this affliction, who have been compelled, from the nature of their occupation, to be on their legs from morning till night, and who have not been prevented from following their duties. Occasionally they suffer during the winter from the effect of cold, in the shape of chilblains, but not, I think, more than others do who are not thus afflicted (at least the congenital.) The limb below the knee will be found much wasted; but although this is the case, yet the muscles still retain their healthy character; the deformity also affects the development of the muscles of the entire extremity, as may be observed in the instances of single varus.

Congenital varus very generally exists without any additional deformity, but cases will be met with in which the knee is also contracted, and in which some irregularity also exists, such as an actual deficiency and malformation, and supernumerary toes, (vide fig. 4). In this case the child had six toes on each foot, and five fingers on each hand, but this does not appear to occur more frequently in cases of varus than it does without any malposition of the extremities. Occasionally there will be found a relaxed state of the ligaments of the knee, which admit of a sort of rotatory motion, the tibia on the femur, which gives an additional amount of severity in the appearance of the deformity, the foot appearing to be *rotated more inwards*. This will require attention in the after-treatment. I have seen

some few instances of incipient lateral curvature of the spine, in children afflicted with single varus, from the excessive motion kept up in the vertebral column from the lameness of one extremity. This increase of mobility between the vertebrae will be found to terminate occasionally in lateral curvature, provided the deformity is not removed, and the motions of both limbs made to correspond with each other. This applies to lameness of one or other lower extremity, from whatever cause such lameness may arise.

Cases of varus will be met with in every amount of severity, both in the infant as well as in the adult. In the former the increased severity arises from a more complete and rigid contraction of the muscles alone, whilst in the latter the rigidity will be found to exist in the muscles; and, secondly, by far the most obstinate resistance will be found in the passive attachment of the bones and joints, viz. the ligaments. In the infant, you will be enabled frequently, with but little force, to place the foot in its natural position, and it will return to its contracted state but slowly, and in some cases the foot occasionally assumes its natural position, but seems to invert itself slightly when the muscles are acting. In others a fixed contraction appears to exist, so that after you have abducted the foot it will return by an elastic impulse to its false position, but this depending on the amount of the muscular contraction. In the case I mentioned in my first lecture the contraction was complete previous to the operation, yet upon examining the tendons a linear cicatrix could be detected, and that only after maceration, and then very imperfectly. And yet the foot was held and maintained in its natural position, and the little patient up to the time of its illness could use it freely in that position.

I have never witnessed any spasm in true varus simply, nor do I think it does exist. The return of the foot to its false position after it has been forcibly held out is not the result of *spasm*, but of the return of the muscles to its contracted position which has thus been forcibly drawn out. Again, where is the evidence of spasm after the cure is effected, when the patient possesses the voluntary movements, and freely exercises them? In fact, as far as my observation goes, there is no diseased or unhealthy action of the muscles contracted. In the adult, and during the period of youth, you will also meet with the deformity in every amount of severity. In some cases a great amount of motion will be found on any attempt to abduct the foot; in others will be found the most firm and unyielding resistance, which appears to depend considerably on the health and constitution of the patient, more so than on the

it was found, had entirely disappeared, and the part which was threatened with sphacelus presented a darkish red gelatinous appearance, with vessels ramifying through it, the surface being continuous with the healthy structure. Flour was now applied to the injured surface, and the extremity was covered with flannel bandages, the strapping being omitted. In the course of three or four hours the foot and leg became immensely swollen, red, and painful, having the acute erysipelatous appearance. The removal of the strapping had completely interrupted the restorative process, by withdrawing the uniform support. The capillaries, already weakened by the paralytic condition of the limb, immediately gave way, and became unable to carry on the circulation, from their dilated and over-distended condition, so that a complete stricture, like that which would have followed the application of a ligature, was formed entirely round the injured part, whereby its vitality was entirely destroyed: the part reassumed its black appearance, the slow process of separation followed, and a large wound was the result, which occupied some weeks in healing. The case, however, was very instructive, as it clearly illustrated the weakened condition of the capillary vessels, and the impossibility of the circulation when at all excited being carried on in parts having the low state of vitality which is frequently found to exist along with paralytic affections.

The consequences of removing the support afforded by the strapping in this case was a sort of self-strangulation of the part: the weakened and dilated capillaries could not withstand the full force of the heart; they became over distended, the blood stagnated in their channels, and the part died from want of a due supply of the vivifying fluid, the blood. I would advise, therefore, that in all cases of this kind recourse should be had to the uniform and constant support afforded by strapping. A bandage, however carefully applied, will not effectually render the absolutely necessary, uniform, and constant support which is attained by strapping. It is well to apply a bandage over the strapping, as it serves to preserve the temperature of the limb. I directed your observation to the necessity of applying a boot and suitable support as soon as the foot was sufficiently flexed, which support must be continued until the weakened muscles have regained sufficient strength to prevent the chance of a relapse. The boot will frequently be necessary for years, as in the case related by Delpsch: it is a great comfort to the patient, and does not interfere with the motions of the joint, nor will the slightest anterior inconvenience arise from its use.

I now proceed to consider particularly that species of deformity called talipes varus.

By talipes varus is understood that kind of deformity which consists, 1stly, in the elevation of the heel, from contraction of the gastrocnemius; 2dly, in the adduction and semirotation of the anterior portion of the foot by the contraction of the anterior and posterior tibial tendons; 3dly, in a shortened condition of the sole, occasioned, 1stly, by the adduction of the foot; 2dly, by the contraction of the plantar fascia, muscles, and ligaments of the sole. In adults you will find also a great increase of the lateral or transverse arch of the foot, which has been brought on by the constant pressure of the weight of the body, in walking on the outer and dorsal surface of the fifth metatarsal bone, which thus becomes approximated to the metatarsal bone of the great toe (vide fig. 2). You will then find the os scaphoides approximated to the internal malleolus, and separated from the external anterior side of the surface of the astragalus. The os cuboides, again, is separated on its outer aspect from the os calcis, and closely pressed on its internal side to the inner edge of the articular surface of the os calcis, and also of the external portion of the anterior articular surface of the astragalus; this being the principal change caused by the adduction of the foot. We have also the almost perpendicular position of the os calcis, as in the talipes equinus, and the oblique position of the astragalus. The fourth and fifth metatarsal bones will also be found separated slightly from the outer side of their articulation with the os cuboides, but the principal change of position is between the astragalus and os scaphoides, and the os calcis and cuboid bone. The anterior portion of the foot remains very nearly in its natural relative position, at least so far as the position of the bones is concerned. The calcaneo-cuboid ligament becomes stretched on its outer portion, and contracted on the inner. The calcaneo-scaphoid ligament is also stretched. The superior and external calcaneo-cuboid will likewise be found elongated. The internal lateral or deltoid ligament is contracted. Of course the other ligaments are all more or less changed from their natural length and position, but those particularly mentioned are the most important. In the increase of the transverse arch of the foot in the adult deformity, you will find the transverse bands contracted, and offering a powerful resistance. The muscles which are contracted, and the immediate cause of the malposition, are, 1st, the gastrocnemius, 2d, the adductors direct, viz. the anterior and posterior tibial, the extensor and flexor of the great toe, as well as the extensor and flexor communis indirectly. The peronei are elongated, or rather kept upon the stretch. The contraction of the ligaments does not apply to infants, but becomes so

FIG. 1.

An illustration of the most severe form of talipes varus, in the adult, taken from the cast of a patient *et. 24*.

FIG. 3.

The cast of figs. 1 and 2, after the treatment, which occupied ten months, in which the remnant of the cushion on which the patient formerly trod is conspicuous.

FIG. 2.

The posterior aspect of the above figure; *a.* illustrating the approximation of the metatarsal bone to the metatarsal bone of the great toe, from the constant pressure occasioned by the weight of the body.

from position. This deformity is both congenital and non-congenital; but in a large proportion it is the most common form of congenital deformity. In the congenital you will find no paralysis; in the non-congenital, paralysis of one or more muscles will very generally be found; and this applies to almost every non-congenital deformity. I have never seen a congenital paralytic affection of any of the muscles in any deformity, nor do I believe that it exists. In the infant you will find the size of the affected limb correspond with that of the well-formed and perfectly proportioned one; but of course, as the child grows, the foot remaining in its false position, and the play of the

muscles in that foot being most limited, the muscles, as a natural consequence, become developed but very slowly; and as the child continues to grow, the limb presents the appearance of an atrophied extremity, the natural outline of well-developed muscles being entirely absent; and yet all this arises entirely from want of use, as no paralysis exists, nor any loss of the voluntary power. The temperature of the limb is natural, but the foot does not resist the effect of cold so well as the naturally-placed foot; but this, I imagine, is entirely owing to its passive condition, and not from any diminished nervous power, or loss of its proper tone; as it is not merely the motion of the ankle-joint that is limited, the muscles which move it are of necessity scarcely if at all able to perform their functions.

There will be found in the adult, and at all periods from the time the patient begins to walk, more or less thickening and induration of the cellular tissue, corresponding to the point or points of pressure, which increases the deformed appearance. In the infant you have the round and natural appearance without any addition to the deformity occasioned by contraction of muscles; and upon examining it you find the anterior portion of the foot entirely perfect (vide fig. 4), and that with some little force, oftentimes, indeed, without any, you will be enabled, by *adduction* simply, to place the foot in a straight line with the tibia and fibula, there being no increase of the transverse arch. Occasionally, but very rarely, I have found the plantar fascia decidedly contracted; and this contraction must have existed some time previous to birth, as the skin will be

found drawn in: this is, however, the exception, not the rule.

The causes of talipes varus (congenital) are supposed by some to arise from mental impressions, or some sudden fright occurring during pregnancy; others think it proceeds from irritation or disease of the brain, its membranes, or spinal chord. Others have supposed that *position in utero* has produced it. It is true, the mother will, in the majority of cases, assign it to some impression or fright; but this appears to me exceedingly questionable and doubtful, as there is scarcely a pregnant woman who during pregnancy, at one time or another, does not receive some fright, and the proportion of deformities as compared with the number born is very small. Again, very frequently the mother will tell you she can imagine nothing nor recollect anything which could have produced the deformity. On the books of this institution many cases of this kind will be found; and then nothing is more common than for patients in general illness being perfectly satisfied that they are aware of the cause of their illness, however wide they may be from the actual fact; so natural is it for the timid to endeavour thus to satisfy themselves. We cannot therefore place much, if any, dependence on these theories. With regard to the brain or nerves of the fetus being diseased, and thus occasioning it, on this I am also sceptical, for there is not a shadow of proof that such has ever been the case. In the first place, the contracted muscles are not in a state of spasm, neither are those on the outside of the foot paralysed or deficient in any respect, more than this, that the adductors have the preponderance, and the abductors have not the power to overcome the adductors; but place the foot in its proper position and you will find that the peronei will hold it out, and during volition evert the foot. The muscles producing the deformity are certainly contracted, but there is no evidence of any irregular action. The patient can at all times exercise the steady well-directed action of the muscles, even in varus, so far as the deformity will allow; and the foot remains perfectly quiet in the absence of the voluntary effort. Direct a boy or adult afflicted with varus to draw up his foot (which we frequently do in order to facilitate the operation), and you will find it is done instantly; direct him also to evert it, and place your hand on the peronei, and you will find them instantly contract, although he may not possess, and does not possess, the power of everting the foot in the least, because of the confirmed malposition. Again, it is a singular fact that at whatever age the patient may be suffering from talipes varus, neither the contracted muscles nor those extended, and which have been extended for years, suffer

in the slightest degree beyond their want of development consequent upon their want of exercise. This would not be the case if there was any disease of the nerves or their centres. Again, take the non-congenital deformity, when the disease or irritation of the brain or spinal chord has been the cause producing paralysis, do we find that we can control or remove the loss of power? Certainly not; it continues; and at present we know of no remedy for complete paralysis, the muscle itself wasting and degenerating into a sort of fatty condition. There are cases where paralysis has been the first symptom, and deformity the result; where every muscle will be found to have recovered itself, and after the restoration of the foot into its position will by exercise maintain the motions of the foot; but this is the exception, not the rule. Whereas in congenital deformity it is quite the reverse, and I have never, as I have before stated, witnessed a *congenital paralytic* condition. I cannot therefore place any faith in the opinion that the malposition arises from such a cause. Lastly, as regards the position in utero: this, I think, the most probable cause, although we can have no proof beyond the fact, that in some of the varieties of non-congenital deformity, position appears to favour contraction, and in my opinion certainly does so; even in cases, you will observe, where the muscles have possessed their power, and have been for years fulfilling their natural functions, yet from being kept in one position they became contracted in that position without any (so called) structural shortening; even the passive organs of the joints themselves become contracted from position without any change in their healthy condition, or, in my opinion, actual shortening. How much more likely should we consider it that a muscle should become fixed and contracted in the position in which it has been kept for a longer or shorter period; therefore, so far as I can judge, I certainly am inclined to regard the exciting cause of the deformity as arising from the position in utero. But we have as yet no proof of this being the fact, and I fear it is not likely we shall find indisputable evidence to establish it.

Patients afflicted with varus have not, as you must perceive, any motions available for walking, in the ankle-joint. They are, therefore, compelled to walk with a perfectly stiff limb below the knee, and the sole of the foot is turned backwards off the ground (vide fig. 2), whilst the dorsum is placed directly forwards (vide fig. 1), the inner portion being elevated, and the anterior portion, including the phalanges, metatarsus, and tarsus, being at right angles with the os calcis, astragalus, and ankle-joint (vide figs. 1 & 2); hence the peculiar appearance and hideous deformity which these unfortunate objects present in walking,

by the anterior portion of one foot being carried over the other during the act of progression, in double varus. In the majority of cases you will find double varus to exist; there are, however, a great number of cases where only one foot is affected. The pain and inconvenience experienced by the patient are frequently very great, from the constant pressure on one point, and that point being an artificial one, whereby inflammation occasionally is set up in the cushion formed by nature to protect the bones, and is followed by supuration, and a tedious wound, during the healing of which the patient is totally prevented from using the limb. Even after the wound is healed great pain and tenderness are experienced, in consequence of the pressure then becoming directed on the bones themselves: the protecting matter having suppurated, has left them, comparatively speaking, exposed. At all times a great degree of lameness and stiffness in walking is the result; and yet many walk miles during the day with comparatively little inconvenience. Cases even occur among persons who are compelled to obtain their existence by their daily labour, but most of these unfortunate creatures follow some sedentary occupation, such as that of a tailor or shoemaker; still we have had one or two instances of agricultural labourers suffering under this affliction, who have been compelled, from the nature of their occupation, to be on their legs from morning till night, and who have not been prevented from following their duties. Occasionally they suffer during the winter from the effect of cold, in the shape of chilblains, but not, I think, more than others do who are not thus afflicted (at least the congenital.) The limb below the knee will be found much wasted; but although this is the case, yet the muscles still retain their healthy character; the deformity also affects the development of the muscles of the entire extremity, as may be observed in the instances of single varus.

Congenital varus very generally exists without any additional deformity, but cases will be met with in which the knee is also contracted, and in which some irregularity also exists, such as an actual deficiency and malformation, and supernumerary toes, (vide fig. 4). In this case the child had six toes on each foot, and five fingers on each hand, but this does not appear to occur more frequently in cases of varus than it does without any malposition of the extremities. Occasionally there will be found a relaxed state of the ligaments of the knee, which admit of a sort of rotatory motion, the tibia on the femur, which gives an additional amount of severity in the appearance of the deformity, the foot appearing to be rotated more inwards. This will require attention in the after-treatment. I have seen

some few instances of incipient lateral curvature of the spine, in children afflicted with single varus, from the excessive motion kept up in the vertebral column from the lameness of one extremity. This increase of mobility between the vertebrae will be found to terminate occasionally in lateral curvature, provided the deformity is not removed, and the motions of both limbs made to correspond with each other. This applies to lameness of one or other lower extremity, from whatever cause such lameness may arise.

Cases of varus will be met with in every amount of severity, both in the infant as well as in the adult. In the former the increased severity arises from a more complete and rigid contraction of the muscles alone, whilst in the latter the rigidity will be found to exist in the muscles; and, secondly, by far the most obstinate resistance will be found in the passive attachment of the bones and joints, viz. the ligaments. In the infant, you will be enabled frequently, with but little force, to place the foot in its natural position, and it will return to its contracted state but slowly, and in some cases the foot occasionally assumes its natural position, but seems to invert itself slightly when the muscles are acting. In others a fixed contraction appears to exist, so that after you have abducted the foot it will return by an elastic impulse to its false position, but this depending on the amount of the muscular contraction. In the case I mentioned in my first lecture the contraction was complete previous to the operation, yet upon examining the tendons a linear cicatrix could be detected, and that only after maceration, and then very imperfectly. And yet the foot was held and maintained in its natural position, and the little patient up to the time of its illness could use it freely in that position.

I have never witnessed any spasm in true varus simply, nor do I think it does exist. The return of the foot to its false position after it has been forcibly held out is not the result of *spasm*, but of the return of the muscles to its contracted position which has thus been forcibly drawn out. Again, where is the evidence of spasm after the cure is effected, when the patient possesses the voluntary movements, and freely exercises them? In fact, as far as my observation goes, there is no diseased or unhealthy action of the muscles contracted. In the adult, and during the period of youth, you will also meet with the deformity in every amount of severity. In some cases a great amount of motion will be found on any attempt to abduct the foot; in others will be found the most firm and unyielding resistance, which appears to depend considerably on the health and constitution of the patient, more so than on the

occupation they may have followed. One of the most severe cases we have had in this Charity, and which was the longest under treatment, was that of a female 24 years of age, of which figs. 1, 2, and 3, are from the cast. But it must be borne in mind that the increased severity in an infant is dependent solely on the greater amount of contraction in the muscles themselves; not so, however, in the adult. In these, the severity will be greatly increased by the

contraction of ligaments, from position, in the muscles, as well as the tone of the ligaments and parts themselves; for the more robust the health of the individual (as a rule) the more firm and dense the resistance. You have also the additional deformity in the transverse arch of the foot in the adult, which is occasioned by the pressure of the weight of the body, to which the infant is not subjected, and which is no slight obstacle. (Vide fig. 2.)

FIG. 4.

Talipes varus of a child seven weeks old, with six toes to each foot, illustrating the round and uniform appearance of the foot, when not subjected to the pressure occasioned by the weight of the body.

FIG. 5.

The casts of the feet represented in fig. 4, seven weeks after the operation; the little patient possessing free voluntary motion. The anterior and posterior tibial tendons, and the tendo-Achilles, were divided in each.

ON THE
PHYSIOLOGICAL CHEMISTRY OF
PROTEINE AND ITS COMPOUNDS.

By PROFESSOR MULDER, OF UTRECHT.

Translated from the Dutch,

By JAMES PAGET,
Lecturer on Physiology, &c., at St. Bartholomew's Hospital.

(For the Medical Gazette.)

WHATEVER is written upon proteine by its discoverer will command attention, and the account of it which is here translated* appears to me both more complete and more compact than any other I have seen. But it is not only for the facts which it contains that it may be read with profit, — another and perhaps greater value is given to it by its enforcing, with the authority of one of the first analysts of the present day, the necessity of a more minute examination of those organic substances which we are apt to regard as having been already thoroughly investigated. Mulder, it is evident, considers his own knowledge of the physiology of the proteine-compounds to be very imperfect; yet their chemical formulæ are often used as if they were as sure as the surest facts. The principle which he holds of the importance of the small and various quantities of sulphur, phosphorus, and other substances, in the several compounds, is (it need hardly be said) identical with that which Dr. Prout has maintained in regard to all those which he has classed as *incidental elements*. It would be opposed to the analogy of all we know of the delicacy and exactness with which the component parts and substances of living beings are adapted to their purposes, if it were to be proved that these elements are not influential in determining the properties and functions of the particles into the composition of which they enter; or that the proportions in which these elements are combined with the four others, however small, are unimportant. Rather, it is probable that the differences of composition in organic bodies by which differences of mutual action are determined, are far more minute than any art of chemistry at present reached can detect. When, for example, we find a morbid material in

the blood, combining with or destroying one portion of a tissue, and leaving unaltered another portion by its side, which to all the powers of observation which we possess appears the very same in all its properties, we ought to be ready to believe that one living organic substance tests the properties of another with a delicacy which is not yet nearly attained by art.

The art by which it may be attained has not among its professors any more eminent than Mulder, nor one more likely to lead others to their own reputation. I trust, therefore, that this translation (which I have in nearly every part made as literally as possible) may be acceptable to those students of physiological chemistry to whom the work from which it is taken is not accessible.

J. P.

A substance occurs in plants as well as in animals, which is prepared by the former, and imparted in their food to the latter, and is of unlimited importance in both the vegetable and the animal body. It is one of the most complex substances; under various circumstances it very easily changes its composition, and it is thus a source of chemical change, especially in the animal organism. It is, beyond contradiction, the most important of all the known substances of the organic kingdom; without it, life, apparently, could not subsist upon our planet; by it the most important phenomena of life are brought to pass.

It occurs in various parts of plants, — in roots, stems, leaves, fruits, and in the juices of all these; it is found in very dissimilar parts of animals. In plants, it is present in three different forms, namely, soluble in water, insoluble in water, and soluble in alcohol; in animals, it exists in various conditions, being either soluble or insoluble in water, and, in the latter case, of various structure. It enters into various combinations with sulphur, or with phosphorus, or with both, and, hence presents as many differences in appearance and physical qualities. It is named *proteine*, because it gives origin to very dissimilar objects, and is thus a primary substance.

We obtain this substance in the form of greyish-white flocculi, by dissolving boiled white of egg in a weak caustic-alkaline solution, and then, by

* From the "Proeve eener Algemeene Physiologische Schekunde," door G. J. Mulder, Hoogleraar te Utrecht. St. IV. pp. 312-344.

adding an acid, neutralizing the solution. It is obtained also by dissolving grain-flour, after it has been kneaded under water and freed from starch, in a similar weak solution, and adding an acid till the alkali is neutralized.

We find proteine in the saps of plants—in all, without distinction; it is found even in the young parts of the roots, and therefore, like cellulose, it is among the substances which are formed immediately from the food of plants. Whether it is also formed in other parts of the plant is not proved; but since the youngest radicles, together with cellulose, contain proteine-compounds, it may be conveyed from them through the whole plant; and to this end its being easily soluble in water may contribute. But, on the other hand, it may pass into the solid form, and being thus deposited in the cells of the plant, may fill them, and form some of its solid constituent parts. In this form we find it in many seeds, of which it may constitute the chief mass. It is in them precipitated proteine formed elsewhere, probably at the extremities of the radicles, and originally existing in solution in the sap of the plant.

This precipitation of proteine in the solid state in certain groups of cells in plants may take place by a simple process. Acids, for instance, change it from soluble to insoluble proteine; and thus the simple presence of an acid is sufficient for this metamorphosis. On the other hand, the insoluble proteine may be redissolved by alkalies; and therefore, after it has been deposited any where in the solid form in cells, the addition of an alkaline fluid may suffice to carry it elsewhere.

Some saps are, by the large quantity of proteine-compounds which they contain, milk-white; in all, for the same reason, a turbidness is produced by heat. In combination with fat oils and water they form emulsions. They are combined with sulphur and phosphorus, bases and salts.

That proteine pre-exists in the plants, and is not produced by the action of the weak ley which is employed for its separation, no impartial observer can either doubt or deny. In the first place, the compounds of proteine which are found in plants have properties all of which completely agree with those of *proteine itself*, if we except those

properties which belong to the substances which are combined with the proteine. Vegetable albumen, for example, a compound of proteine with sulphur and phosphorus, has all its properties in common with proteine, those only excepted which belong to sulphur and phosphorus; and if we add to this that the per centage composition of proteine and albumen is the same, provided we take away the sulphur and phosphorus which are combined with the latter, the pre-existence of proteine in plants cannot be a matter of doubt.

The formula of proteine, calculated from its analysis, as well as from various combinations into which it enters with acids, is $C_{40} A_{62} N_{10} O_{12}^*$.

In plants proteine occurs combined with sulphur and phosphorus; but how they are combined is not yet known. These compounds were formerly named *soluble albuminous matter*, *coagulated albuminous matter*, *legumine*, and *vegetable gluten*; names of which the first three have been changed by Liebig into those of *vegetable albumen*, *vegetable fibrine*, and *vegetable caseine*. These names, to be good, ought to be founded on the conformity of these three substances with three proteine compounds of the animal kingdom—albumen, fibrine, and caseine; but this conformity is not proved. The small quantities of sulphur and phosphorus by which these last differ from each other and from pure proteine determine their character. And since the quantities of sulphur and phosphorus in the three first-named vegetable substances are as yet unknown; one cannot use these names for them. Moreover, coagulated vegetable albuminous matter and legumine differ

* Mulder gives here only the results of his analyses; they are fully detailed in his original paper on proteine in the Netherlands Bulletin des Sciences, 1838; and an account of them is given in Simon's Handbuch der Medicinischen Chemie, Bd. i. S. 41, &c. I have not reduced Mulder's formulæ to those by which the composition of the same substances would be represented according to the equivalent numbers more commonly adopted in this country, because, had I done so, some of his calculations would appear erroneous. He takes for the equivalent of oxygen 100; that of carbon, the basis of his other estimates, he makes 76.437, which, on the hydrogen-unit scale, would be 6.115; and those of hydrogen and nitrogen 6.24 and 88.36; water being represented by the formula H_2O . From these data the reader may reduce the formulæ to his own mode of calculating. If carbon be taken at 75 (or 6 on the hydrogen-unit scale) the number of equivalents of hydrogen in the formula for proteine will be, as Simon gives it, 60 instead of 62.

so much in form and appearance from animal fibrine and caseine, that they cannot be called even by names of the same kind. We continue therefore, till the identity of these substances is proved, to call *legumine* the substance which is obtained in white flocculi from peas and beans, when, after they have been ground fine and treated with warm water, the solution has been filtered and precipitated by an acid. *Vegetable albuminous matter* we name the substance which is soluble in water, precipitable from saps by heat, alcohol, and acids, soluble in weak alkalies, and precipitable from its alkaline solutions by acids; and which, setting aside the sulphur and phosphorus, presents itself on analysis as proteine. *Coagulated vegetable albuminous matter* is the compound of proteine, sulphur, and phosphorus, which is insoluble in water, and occurs in seeds, *e. g.* in those of the cerealia, in almonds, &c. *Vegetable gluten* is the substance which can be extracted from raw gluten by alcohol. The formula of vegetable gluten from wheat is $10(C_{44}H_{88}N_{10}S_{12})S_2^*$.

It was proved that the chief constituent of the animal body is prepared by plants, and that animal fibrine, albumen, and caseine, differ only by small quantities of sulphur and phosphorus, and when similarly treated with alkalies yield the same proteine as coagulated vegetable albuminous matter; and Liebig has more lately found a similar agreement between the four vegetable substances just mentioned, deduced from the quantities of carbon, hydrogen, and nitrogen, which they yield in elementary analysis. By these analyses it is determined that all these substances are proteine-compounds; but there is still much wanting for a complete knowledge of them. In every case they contain proteine com-

pounds, which, transferred into the animal body, convey the proteine unaltered; so that what digestion has to alter in these substances to make animal substances from them, consists first in the solution of the insoluble vegetable albuminous matter and vegetable gluten, and then in the changing of the quantities of sulphur and phosphorus, which are probably different in the vegetable proteine compounds from what they are in the animal.

Vegetable gluten and coagulated vegetable albuminous matter are obtained by kneading wheat-flour under water to remove the starch, and when this is sufficiently accomplished, by treating what remains with alcohol. What now remains undissolved is the so-called coagulated vegetable albuminous matter, still containing starch, from which it may be freed by boiling in water. Further, it contains cellulose. If therefore it be in this state subjected to elementary analysis, we obtain the results of an analysis of a mixture of vegetable albumen and cellulose. Jones has on this account obtained too little carbon in his analysis* of his substance thus prepared. But there is no other means of separating the cellulose and vegetable albumen in this mixture besides that of changing the albumen into proteine, that is, by removing the sulphur and phosphorus which are in the albumen, or, in other words, by separating them from the proteine, by their combination with which the vegetable albumen is formed. This is effected by potash: a weak ley dissolves the proteine out of the mixture already mentioned, oxydizes the phosphorus, forms with the sulphur sulphuret of potassium, and leaves the cellulose undissolved; then, if a weak acid be added to the clear solution, proteine is precipitated. But no means are known for obtaining pure coagulated vegetable albumen. In all the seeds in which it occurs it is mixed with cellulose, for which no solvent is known which would leave the albumen; and if the albumen be dissolved, so as to leave the cellulose, the albumen is changed into proteine. Pure coagulated vegetable albuminous matter (the pure vegetable fibrine of Liebig) is thus as yet unknown, and we know not how large is the quantity

* This is deduced from analyses very recently published by Mulder (Scheikundige Onderzoekingen, Deel. II.) The results of two analyses gave—

	I.	II.	Equiv.	Calculated.
C	54.93	54.75	400	54.89
H	7.11	6.99	620	6.94
N	15.71	15.71	100	15.90
O	21.68	21.93	120	21.55
S	0.87	0.62	2	0.72

Among former analyses, those of Dr. Bence Jones, in Liebig's Organic Chemistry, &c. p. 295, most nearly agree with these. These also, like Dr. Jones's, were made from the portion of raw gluten which is soluble in alcohol; but in his formula the sulphur is put down with the oxygen, and the proportion of hydrogen is importantly higher.

* The analysis of vegetable fibrine may be found in Liebig (l. c.) p. 294.

of sulphur and phosphorus combined with the proteine.

That portion of the substance remaining after the kneading of wheat-flour in water, which is soluble in alcohol, is named *vegetable gluten*. It precipitates from the alcohol when it cools, or on adding water, in white flocculi; but another portion, combined with gum, remains dissolved in the weak alcohol, even when it is diluted with a considerable proportion of water. It is, when moist, very tenacious, tough, and elastic; when dry, it is a semi-transparent substance, very hard, difficult to pulverize, insoluble in water, and partaking of all the properties of the compounds of proteine with sulphur.

It is probable that this compound is not a pure chemical body; at any rate, when we treat it with acetic acid, it nearly all dissolves, but there remains a small quantity of some substance which is insoluble in acetic acid, which makes the solution turbid, and cannot be separated by filtration. Our knowledge, therefore, of the true nature of vegetable gluten is incomplete, although we know that it is a sulphur-proteine-compound.

Vegetable albumen occurs in plants with properties similar to those which we find in the animal albumen in the serum, in eggs, and a number of other substances. Every fresh vegetable sap yields it, on being heated, as a coagulum. This is the form in which it is, in the first instance, prepared in plants, and from which, without doubt, the other proteine compounds of plants (the coagulated albuminous matter, &c.) take their origin. Coagulated by heat from saps, it incloses chlorophyll and other substances. It is obtained pure from wheat flour by heating the water in which the flour has been kneaded, and the starch has fallen to the bottom. Albumen then coagulates, and, after being boiled with water and alcohol, is pure vegetable albumen. Its constituents (leaving out the sulphur and phosphorus, which are not yet determined) are exactly the same as those of animal albumen.

Legumine is a substance, like gluten, which is especially abundant in peas and beans. When dissolved in water, legumine is precipitated by alcohol, in a solution in which it

acid reaction; freed of this, it is insoluble in water. After being dissolved in ammonia, and precipitated from the solution by an acid, and then treated with alcohol, it is pure, and a proteine compound; but what, we know not.

From this short account of the four proteine-compounds at present known in plants, it follows that there are two which are soluble in cold water, viz. albuminous matter and legumine, of which the former is, the latter is not, coagulated by heating its solution; and that there are two others which are insoluble in water, viz. the so called coagulated albuminous matter and the vegetable gluten, which last is dissolved in alcohol.

Similar substances are also found in the animal body, differing from one another by small ingredients and combinations. As legumine and vegetable gluten differ from vegetable albumen, so also does caseine differ from animal albumen. There is not more than an approximation in properties and composition between these substances; and we are ignorant of their essential composition, so long as the small ingredients are unknown to us.

The known proteine-compounds of the animal body are as follows:—

The fibrine of the blood is composed according to the formula—

The albumen of the serum of the blood—

The albumen of hen's eggs, like fibrine.

The caseine of cow's milk—

The substance which forms the chief constituent of the crystalline lens—

* These formulae are calculated from the original analyses published by Mulder in the papers already referred to. The results obtained by Berchard (see Liebig, l. c. p. 310) do not materially differ from Mulder's. Those of Dumas differ slightly (Annales de Chimie et de Physique, 33), but Mulder passes these by as being not of accuracy. On the analysis of the lens freed from oily matter by ether, Dr. Henry Jones (Liebig, l. c.) has said, "It appears to be genuine albumen."

And in an account according to the analysis of vitelline made by Berchard, it was found at 120°

These are the known proteine compounds of the animal body. But we know, besides, with certainty, that the muscular fibres are a proteine compound; that in the brain, liver, kidneys, and many other organs, proteine compounds are met with under the forms of albumen; that a proteine compound is found in horns, nails, cuticle, and hairs; that oysters consist almost entirely of proteine compounds; that silk and spiders' webs also contain one: but what proteine compounds these are is as unknown as it is what compounds the vegetable albuminous matter, the legumen, and the coagulated vegetable albuminous matter are. Science has still to fill up these chasms. Very small quantities of sulphur and phosphorus, and perhaps of other substances besides, may produce the physical and some chemical differences which we observe in all these bodies. We, therefore, do not regard all these substances as identical (although they present on analysis almost the same per centage composition), any more than we consider starch and gum, which by per centage are similarly composed, as the same substance; and yet further, in many of them, we have, by examination, detected differences in the quantity of sulphur and phosphorus, and we must therefore regard most of these substances as chemically essentially different. But they all, without exception, have the same organic compound for their chief constituent; a constituent which pre-exists in all, and which thus permits an easy transition from one to the other.

It is of great importance to observe this, because nature, by combining small ingredients with one and the same

radical substance, or by removing them from it, produces many, and apparently very dissimilar, substances. We see here a very remarkable uniformity, and yet we find, in chemical difference, however small the quantities may be, the cause of difference in the nature and quality of the substances. It is, therefore, no polymorphism which gives rise to the differences in the before-mentioned proteine compounds, but essential chemical difference in material composition; and it is, therefore, still a question, to be solved only by the most laborious and careful analyses, wherefore and in what the several proteine compounds differ from one another. Science has to make out not only that a proteine compound occurs in grass, and that the ruminant animals thence derive their proteine compounds, which they daily yield in large quantities in their milk, but it has to be proved whether the proteine compound of grass, as well as that of milk, has sulphur but no phosphorus combined with it; whether the quantities of these ingredients are or are not different, and, if they be, in what way the difference is produced in the animal body. Certain as it is that caseine and albumen are very different from one another, and important as it is to know this difference, so is it indispensable to demonstrate on what the difference depends. The fact that plants prepare the proteine for animals being once known and settled, these questions are amongst the first which it belongs to science to resolve.

I purposely speak emphatically on this subject, because I do not believe that the small quantities of sulphur and phosphorus are indifferent ingredients, but that, on the contrary, these substances play an important part in the organism, albeit they constitute only fractions in the per centage reckoning. It is not the quantity of the substances that are combined which determines the degrees of difference in compounds, but the presence or absence of other bodies. Arseniuretted hydrogen (H_2A_2), one of the most dangerous gases, contains 98.05 of arsenic and only 1.95 of hydrogen; but it is by means of this hydrogen that the gas is not metallic arsenic, and presents its peculiar properties.

[To be continued.]

ON THE SURGICAL TREATMENT
OF PHTHISIS PULMONALIS.

To the Editor of the Medical Gazette.

SIR,

WHEN two or more persons residing at a distance from each other happen, about the same time, to arrive at similar conclusions, the rule generally, and most wisely, acted upon is, to assign the chief credit to the individual who first lays his views before the public. In accordance with this maxim, the merit of the discovery of a novel, and, as it appears to me, a very promising, plan of treating cases of advanced phthisis pulmonalis, will be awarded to Dr. Von Herf,* of Darmstadt, who, as I saw by the *Times* newspaper of Monday last, has already carried into effect ideas precisely similar to certain notions which I had previously entertained, and for testing the accuracy of which I had resolved to avail myself of every opportunity that might occur.

As these views, however, were merely entered at the time in a private memorandum book, I shall, in the present communication, do no more than state briefly some of the considerations which suggested themselves to me, as calculated to inspire just grounds of hope in the efficacy of the proposed measure, as a means of mitigating the sufferings and prolonging the existence of those affected with this dreadful disease. And as the question of the propriety of this procedure must shortly engage the attention of the profession in this country, the few rough notes which I made on the subject may possibly, in the present early stage of the inquiry, not be without interest to some of your readers.—I am, sir,

Your obedient servant,
GEORGE ROBINSON.

24, City Road, Sept. 12, 1844.

One great cause of the inability to cure, or even materially to relieve, cases of confirmed phthisis, is to be found in the apparent impracticability of discharging the tubercular and purulent matters in any other manner

than through the trachea. For as, from the peculiar nature of their functions, the passage of air to and from the lungs cannot be suspended for the shortest time without instant suffering and speedy danger, so great evil necessarily results to the phthisical patient from the circumstance of the large air-tubes being, at one and the same time, engaged in conveying copious, irritating, semi-solid masses, from the tubercular cavities, and in transmitting a supply of respirable air to the unaffected portions of the organ. Thus

1. The presence, in the air-passages, of these acrid discharges causes frequent and violent fits of coughing, by which the individual's rest and comfort are destroyed, his strength exhausted, and the pulmonary circulation more or less disordered.

2. They excite a sub-acute inflammation of the bronchial tubes, the copious effusion from which still further increases the difficulty of respiration.

3. The accumulated matters must occasionally be brought in contact with the contiguous portions of healthy lung; and, whether considered as simple irritants, or as conveying the exciting cause of a specific morbid action, the effect of their application will inevitably be the gradual disorganization of the surrounding tissues, by the arrest of the circulation through them.

4. It appears to me by no means improbable that the absorption, by the blood-vessels of the healthy lung, of a portion of the semi-putrid matter resulting from the decomposition of the tubercular masses, may not only cause the colliquative diarrhoea and sweating, peculiar to the latter stages of the complaint, but may also induce the formation of similar deposits in other parts of the body, by effecting a change in the blood itself.

These considerations may suffice to show how much the difficulty of curing the disease is augmented by the long, tedious, and inconvenient route along which the expectorated matters have to pass. And I shall now proceed to enumerate some of the reasons which suggest themselves in favour of the plan of making a direct opening from the exterior of the thorax into the ulcer or suppurating cavity.

First in the list must be mentioned the possibility of discovering with too

* I did not see the *Times* until the second day after its publication; and, though I made a hurried memorandum of the name of this gentleman, I cannot be certain that I have copied it correctly.

lerable certainty, by the stethoscope, the precise situation of the disease.

2. In post-mortem examinations, cicatrices have been found in the lungs; thus establishing the fact of the curability of pulmonary ulcers. And, were it equally accessible, there is no reason why a scrofulous abscess of the lungs should not be as amenable to treatment as one of any other part of the body.

3. The portion of lung affected with tubercular deposit is generally glued by pleuritic inflammation to the corresponding surface of the thorax. And this is perhaps the most important fact that can be adduced in favour of the proposed operation. For, in consequence of this occurrence, not only has the affected part the advantage of rest, but it is also, so to speak, rendered a part of the thoracic wall. Hence, any fluid matter contained within it may escape through an external opening without any danger of passing into the pleural cavity.

4. That a pulmonary fistula may exist for a length of time, and then be cured, without any danger to the individual, is, in addition to other facts on record, fully established by two cases related by Le Dran*, in both of which pleuritic (?) purulent effusions escaped, partly through the bronchial tubes, and in part through openings in the thoracic walls. So that an injection into the latter "instantly excited a violent cough, and part of it passed by the mouth mixed with pus." And yet one of these persons, an old lady, aged 73, and a cousin of Le Dran's, entirely recovered; and the other, after living several months with these fistulæ, at length died of another complaint.

The proposed measure being supported by these, and other reasons that might be adduced, the next step should be to ascertain how far its execution is compatible with the safety of the individual. And though the necessity for this proceeding previous to any operation upon the human subject is, to a considerable extent, removed by the account of the success attending the practice of the German physician, there

still remain some points which cannot, in my opinion, be satisfactorily elucidated in any other manner.

The two chief evils likely to result from a direct opening being made into the seat of disease are pulmonary hæmorrhage and pleurisy. Any additional irritation produced by the slight wound of the lung would probably be more than counterbalanced by the increased facilities afforded for the discharge of the pent-up matters. With regard to the danger of injuring some large blood-vessel of the lung, it is to be observed—

1st. That the probability of this occurrence will be diminished by the solidification, and consequent obliteration of the blood-vessels, of the lung immediately surrounding the diseased part.

2dly. That if any active or protracted hæmorrhage did occur from this cause, an astringent solution, or a piece of caustic, might be introduced through the external wound, and other means used to arrest the hæmorrhage.

It now only remains to say a few words on the liability of the operation to produce pleurisy, as a consequence of blood or pus escaping into the cavity of the serous membrane. The chance of this taking place will of course mainly depend upon the degree of judgment shewn in the selection of cases. Until more information is obtained it will probably be well to confine the operation to cases where the stethoscopic signs leave no doubt of the existence of a suppurating cavity near the surface of the lung. And under such circumstances adhesions will generally be found to unite the contiguous surfaces of the pleuræ covering the diseased part of the organ.

But perhaps there would be a greater certainty of finding this desirable union effected, were the operation performed somewhat in the following manner:—The situation being fixed upon, let a tolerably free incision, say an inch in length, be made through the skin and subjacent cellular tissue; and then let the opening into the tubercular abscess be finally accomplished by the repeated application of potassa fusa to the bottom of the wound. In this manner a most effectual counter-irritation would be excited, which alone must prove advantageous; at the same time that the slight inflammatory action surrounding the slough

* See an English translation of his *Observations on Surgery*, published in London, 1758, pp. 116 and 132. I may remark here that it was the perusal of these observations, some months since, that first suggested to my mind the feasibility of artificially establishing, in some forms of pulmonary disease, a similar direct communication between the smaller air-tubes and the exterior of the thorax.

would be very likely to cause adhesion of the subjacent pleure, if it did not previously exist. This question I purpose to endeavour to decide shortly by some experiments; and if a circumscribed adhesion of two serous surfaces can, in any manner, be artificially effected, it will not only remove a chief objection to the operation as at present proposed, but will also render it applicable in various other diseases.

ON THE
NATURE OF TIC DOULOUREUX.

To the Editor of the Medical Gazette.

SIR,
AN amiable warfare has been raging for the last few weeks between sundry gentlemen*, each of whom claims for himself the merit of *discovering* the true nature of neuralgia. Dr. Black says: "the affected nerves being contained in rigid canals must be subjected to injurious pressure whenever the accompanying vessels are unusually distended with blood," and, according to Dr. Wallis, "upon this pressure depends the neuralgic paroxysm." Dr. Skae, of Edinburgh, then descends upon the combatants, robs them of their glory, and annihilates their pretensions to originality by pointing to a paper of his, containing the same theory, which appeared in a Scotch journal in 1840. As, however, there is nothing quite new under the sun, even Dr. Ebenezer Skae must yield the palm to predecessors. "A nerve," says Bichat—and this pathologist spoke long prior to 1840—"a nerve morbidly excited will produce exaltation of function by vascular congestion and irritation of the nerve itself, perhaps even of contiguous parts, from which it derives its arteries, upon the due performance of which its ordinary function depends. And since local determinations of blood to the surface are found to produce an excessive development of nervous energy, as is proved by its influence upon the capillaries in increasing heat, it is probable that *congestion of the vessels of the neurilema* may produce similar results in the ultimate distribution of a nerve."

Martinet, too, was of the same opinion, and his recorded theory of tic douloureux is, that in every instance

it depends upon "vascular congestion of the neurilema," which he found, in several examinations, to be "morbidly thickened, accompanied by a reddish or violet tinge, and spotted with minute ecchymoses."

Dr. Ley, in his Essay on "Laryngismus Stridulus," published in 1836, says, "Local determinations of blood increase the development of nervous energy;" and he agrees with Bichat that excessive pain may be produced by injurious pressure from the congested neurilema.

Having recorded these authorities, I ventured to draw the following conclusions in my work on Tic Douloureux, published in 1841:—"The progress of tic douloureux appears to be as follows: First, disordered function from irritation of the proper nerves of the organ, arising from some noxious influence or impression (the proximate cause), which exhausts the nervous influence whence the capillaries derive their power. They thus become weakened, allow of over distension, and are in a state of passive congestion or hyperæmia."

There are more opinions, I believe, to the same effect, and, after all, they are but *opinions*, for the great objection appears to be, that the pain will frequently shift its seat from one spot to another, distinct and remote, long before the vessels of the neurilema could by possibility become sufficiently turgid to produce injurious pressure.

I am, sir,

Your most obedient servant,
R. H. ALLNATT, M.D.

Parliament Street, Whitehall,
Sept. 10, 1844.

A FEW PRACTICAL HINTS
ON
THE TREATMENT OF HARE-LIP.

BY JOHN CHARLES HALL, M.D.

(For the Medical Gazette.)

I BELIEVE more cases of hare-lip have been under my care than generally come under the notice of those who are not connected with an hospital; and I therefore venture to offer a few hints on the mode of procedure in the treatment. During the last three months I have operated in four cases; three of the children were recommended to my care by medical friends residing in Work-sop, and were under three months old;

* Query—in Edinburgh?—Ed.

and one, brought to me a week ago, was more than three years. In one case a considerable portion of the upper jaw was wanting; in another there was a fissure of the palate; the other two presented nothing unusual. The points to which I purpose to direct attention are—1st, *the best age for performing the operation*; and 2dly, *the way in which it ought to be done*.

First, as to the best age for performing the operation. It has ever appeared to me that an early removal of the deformity must be very desirable, and I see no good reason for keeping the parents for two or three years in a painful state of anxiety. It is true that infants are liable to convulsions after operations; but they are certainly exposed, in some degree, to the same danger at two or three years old; although we should decline operating on very young children therefore,—children of a few weeks old,—I certainly think it unnecessary to wait until they are two or three years old before interfering. Le Dran operated on children of all ages, even at the breast, and B. Bell operated with perfect success on infants under three months old. In the three cases recently under my care (from Workson), not one was more than three months old; one was only nine weeks, and the other ten. In another case operated on by me, at Clayworth, four or five years ago, the child was only seven weeks old; and each case recovered without a single bad symptom. In another case in which the operation was performed on a child nine weeks old, all went on very well for two days; when the nurse, neglecting the infant, allowed it to tear out the pins; in this state it was brought to me. At the request of the parents, but I will own against my own inclination, the edges of the wound were pared a second time, and fresh pins introduced; in three days the pins were withdrawn, and the only inconvenience experienced was a slight scar where one of the first pins had been forced out; this, however, shortly filled up, and the child is now perfectly well, the operation having proved altogether successful. With these and many other similar facts before me, I am led to think that the dangers or inconveniences of operating early have been much overrated. On looking at authorities on the subject, however, I find that I am not singular in this

opinion:—Mays, for instance, says “the operation ought to be undertaken as soon as the child is *six months old*;” but Roonhuysen, who was a celebrated operator for hare-lip, selected *ten weeks after birth* as the best age for operating. Baron Dupuytren justly considers it as dangerous to operate on new-born children, “because their flesh is so soft that the pins readily cut through it;” and because the general mortality, independent of every other cause, being at this age greater than at any period of life, it would be imprudent to augment the chances of death which are suspended over the young child, by an additional one resulting from the operation. Taking every circumstance into consideration, the result of his experience induces this distinguished surgeon to conclude “on the whole, that the best period for operating is when the infant is three months old” (*Leçons Orales*, t. iv. p. 90-92). Again, Mr. Cooper remarks, “a child three or four years old has a thousand times more dread of pain than of the deformity, or of the inconveniences of the complaint to which he has been habituated; while an infant fears nothing, and only feels the pain of the moment” (*Dictionary*, page 655.)

Looking at the advantages of operating early, the comfort it affords the child, the pain and distress it spares the parents, it appears to me advisable to operate before the time of teething. We have the high authority of Baron Dupuytren for *three months* as the best age; a time at which, in the great majority of cases, I am confident the operation may be performed with the most perfect safety and success. Of course there are cases in which it may be prudent to wait until the child is five months old,—cases in which there is a bony projection (as in Mr. S. Cooper's case), which it would be dangerous to cut away, and which can be, in some degree, reduced by the daily application for a few hours of a spring truss; still, in such a case as this, I would not delay the operation beyond five months (the period at which this distinguished surgeon operated with the assistance of the late Sir A. P. Cooper), a period selected as the latest previous to the feverish excitement more or less present during the period of dentition, at which the operation ought to be resorted to.

2nd. The way in which the operation ought to be performed. If there be great diversity of opinion as to the time for proceeding to remove the deformity, an equal difference of opinion exists as to the mode in which the operation should be performed, and particular knives and scissors, pins and ligatures, have each their advocates.

I wish to claim nothing new for the plan of operation that I have found successful; our object is to make as even a cut as possible, in order that it may unite by the first intention, and leave nothing but a slight narrow seam: this may be effected in several ways: the patient, however, must first be secured by a large cloth wrapped round his body: one corner of the lip is then taken up between the finger and thumb, and drawn tight, and the point of a straight sharp-pointed bistoury entered close to the nose and drawn downwards until it cuts its way out at the lower part of the lip. The same plan is then followed on the other side, and the incision made exactly the same length as the first; the slips are then cut out from each side, and made to unite at a very acute point; the incisions must have been so formed as to enable the divided edges to be brought into the most exact contact; we must have no wrinkling, no riding of one cut surface over the other, no deficiency at the lower part of the wound, nor must space be afforded between the cut surfaces for blood to accumulate. Having lain aside the knife, a common sewing needle (the head of which has been covered with sealing-wax,) must be introduced near the upper, and another at the lower part of the wound, *close to the free margin of the lip*, and so placed that the parts may be, on each side, perfectly on a level. The needles ought to be introduced some distance from the edge of the wound, and also through at least two-thirds of the thickness of the lip, otherwise they are apt to cut their way out before the cut edges are sufficiently united. If the pins are not introduced through a considerable portion of the substance of the lip, a narrow groove is left, in which portions of the food accumulate; there is, however, another, and a much more important reason, for placing the pins deeply, and thus bringing the posterior edges of the wound into contact: when so placed the bleeding imme-

diately ceases; but when the pins are placed less deeply the bleeding continues, and causes much trouble, and even places the patient's life in danger. If memory serves me, Louis mentions a case in which, from neglecting to place the pins properly, the patient died.

When the pins are properly introduced, strong silk, well waxed, is to be passed round them in the usual manner, care being taken to draw it only sufficiently tight to bring the edges together, and not, as I have seen it, pulled so hard as to cut out a circular portion of skin over the middle of each pin, which separates in a day or two, leaving a very ugly scar: after the silk is secured the ends of the pins must be cut or broken off with a pair of nippers: no dressing of any kind is required, except a narrow strip of plaister between the pins and extending some distance on either side of the face.

After the pins have remained three whole days, they must be carefully withdrawn; a little olive oil, or warm water, having been first applied to the upper pin, and then, taking hold of it with a pair of forceps, it is to be gently turned round and carefully withdrawn: the silk will probably remain a few days longer, and a long strip of plaister is now to be applied over the threads from cheek to cheek; the lower pin is next to be withdrawn in a similar manner, and the same support afforded.

I have only as yet considered simple cases of hare-lip; when we have a double fissure the operation must be varied to suit the peculiar circumstances of the case; however, in the majority of cases, we may proceed at once as in single hare-lip, and by passing the needles across the two wounds, and through the intervening flap, I have found that the parts are easily brought together, and retained in contact—a plan, in my opinion, preferable to performing two operations at an interval of some weeks.

To recapitulate:—It appears 1st, that we may operate in hare-lip when the infant is three or four months old with safety and success, and that there is no good reason for delaying the operation beyond that period. 2dly. The operation may be performed as above described (and this plan is adopted by Mr. Liston), or by fixing a piece of wood under the lip, and then placing

the parts on the stretch, to cut away the whole of the callous edge, a way of operating calculated to give much more pain than the far more simple mode of Mr. Liston; or we may use a very nice pair of scissors, invented by Savigny, of St. James's Street. My attention was first drawn to this instrument by my friend Mr. Lane; I have since used it in several cases, and have every reason to recommend these scissors to my professional friends. 3dly. Care must be taken to introduce the needles sufficiently deep, for the reasons already stated; to bring the cut edges together as evenly as possible, which cannot be accomplished unless the parts are freely cut away, particularly that *red rounded substance always present at the lower part of the fissure, which, if not removed, will leave considerable deformity*; and lastly, when the pins are introduced, the parts must not be made hot by loading them with all kinds of useless applications, nor must they be withdrawn until time has been afforded to allow the adhesions to become sufficiently firm. I am aware that to the experienced and practical surgeon this paper can offer nothing that was not previously perfectly familiar to him; to the younger surgeon, however, it may, I trust, afford some useful information, and supply him who is about to operate for the first time with hints by which he may avoid those difficulties which all are alike liable to encounter, when undertaking for the first time that with which we are not practically acquainted.

Grove Street, East Retford,
August 6, 1844.

CASE OF ACCIDENTAL UTERINE HÆMORRHAGE,

IN WHICH THE MEMBRANES WERE RUPTURED, AND LARGE DOSES OF ERGOT OF RYE ADMINISTERED.

To the Editor of the Medical Gazette.

SIR,

ON the morning of the 30th of August, 1843, I was urgently requested to visit Mrs. P., æt. 35, a stout corpulent lady, in the last month of her fifth pregnancy. She had risen at an early hour to arrange some domestic matters, but had returned to bed quite well, and in half an hour was seized with alarming flooding.

On my arrival, she was found lying

in a pool of blood, deplorably sunk. The countenance was anemic and cadaverous; surface very cold and clammy; pulse at times entirely gone, and in scarcely an audible voice she said she was dying; abdomen was pendulous, flabby, and yielding throughout; the flow continued, and she had no labour.

The vagina was immediately stuffed, the abdomen supported by a proper compress and roller, and from time to time small quantities of brandy and water were administered. In about half an hour pulse somewhat rallied, and on making inquiry into state of os uteri it was found soft, but only admitting point of finger; membranes were entire, but closely embracing head, which presented high; no portion of placenta could be detected. During this examination, though gone about with all convenient speed, a considerable quantity of blood was lost, and pulse again became imperceptible; at times she seemed in a fatal syncope, while with the tampon, and additional support to abdomen by the hands of assistants, an attempt was made to arrest the hæmorrhage. In addition to the stimulus, she commenced taking ergot of rye, in two-drachm doses, by way of infusion, every twenty minutes: an ounce of the drug was taken with little apparent effect. On a second examination, however, os uteri was found more dilated, and the membranes could be felt somewhat distended, and threatening to protrude; with considerable difficulty they were reached, and scratched through: still the flooding threatened to continue, and if possible a more alarming state of prostration ensued: constant retention of plug, and uniform persevering compression to abdomen, were demanded. In vain I waited upwards of half an hour for uterine contraction, when the ergot was resumed in two-drachm doses, after the second of which, three powerful pains in rapid succession ushered into the world a large still female child, a massy placenta, and a basonful of coagula. Child was pale and perfectly bloodless, and uterine surface of placenta was coated with a layer of coagulum half an inch thick. Uterus remained firmly contracted, and although patient lay in a very depressed condition for some time, suffering much from pulsative headache and œdema of lower limbs, she had a good recovery.

a comparison I believe I had more still births without the ergot than with it; and many cases could be adduced in which the ergot must have been in the circulatory system of both mother and child six hours previous to delivery. I shall as briefly as possible just allude to two cases which I had lately, as they tend to controvert the opinions of those who insist upon the poisonous action of the ergot in foetal life. The first was a breach presentation, first confinement, peculiarly severe, and lasting twenty hours; the second was a head presentation, a fifth confinement. In the first, four drachms of the drug were given in divided doses, and I feel assured that three-fourths of that quantity would be in the circulatory system three hours before the expulsion of the child: it was asphyxiated, but no more difficulty was experienced in resuscitating than in breach cases to be met with every day; there were no convulsions, and in every respect mother and child did well. In the second, the drug was administered on account of irritation; six drachms were given before any efficient pains commenced, and I feel positively sure that two-thirds were taken three hours before expulsion; the child was lively, and continued so. I have every reason to believe that the ergot was of the best quality.

For eleven years I have used the ergot of rye very extensively, and with considerable success, and from all that I have experienced I feel myself called upon to state that I am still of the old opinion in regard to its injurious effects, not as a poison on the foetal system, but acting as a mechanical agent through the instrumentality of the uterus, obstructing the circulation, and thereby causing asphyxia or death, according to the degree or continuance of the pressure. If the drug is as deleterious as some would affirm, it occurs to me that we would have more still births, for surely before the uterus can be acted upon the ergot must enter into the circulatory system, and be ready to manifest its destructive powers immediately, so that whether the birth took place within two, four, or six hours after the administration of the drug, we would be alike unsuccessful.

From what has been advanced, let it not be supposed that here the unlimited use of the medicine is advocated;

it is a valuable, and at the same time a dangerous remedy, and therefore ought not to be indiscriminately given. In first cases, excepting when the breach presents, I never give it, and it is quite inadmissible in unnatural presentations.

I am, sir,

Your obedient servant,
ROBERT PATERSON,
Surgeon.

Glasgow, 204, Argyll Street,
Sept. 1844.

ANALYSES AND NOTICES OF BOOKS.

"L'auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

ACTONIAN PRIZE ESSAY.

Chemistry, as exemplifying the Wisdom and Beneficence of God. By GEO. FOWNES, Ph. D. London, 1844. Churchill.

WE are not sure that chemistry is the best, nor even a favourable, subject for illustrating the wisdom and goodness of God. The actions of chemistry, carried on as they are between the ultimate atoms of matter, and at distances infinitely small, seem to our mind to want grandeur, scope, dimensions, commensurate with argument so high. Nor do we see that any inferences in point are deducible even from the ultimate laws of chemical science: the weight and combining proportions of the atoms of matter might apparently have been anything else than they are, and the evidences of the wisdom and beneficence of the Supreme Being remained precisely as they are, the argument for design and contrivance neither enhanced nor lessened thereby. We see invariability, universality, in these laws, indeed; and therein note and admire another link in the wondrous chain of creation; but the subject is beyond the eyes of common men, and he who wrote his power in the starry firmament and the green earth probably never meant that evidences of his being and attributes should be sought for in philosophic chemistry. Mr. FOWNES, in writing his essay, appears to have felt this: and his work is much more of a treatise on physics and physiology than on chemistry, strictly so called. The subject is in fact discussed under the following heads:—1. The chemical history of the earth and atmosphere.

2. The peculiarities which characterize organic substances generally. 3. The composition and sustenance of plants. 4. The relations existing between plants and animals. Surely there is harmony between the earth and the atmosphere, and the living things that inhabit the one, and draw life in so mysterious a way from the other; these living things could not else have been. Surely, too, there is harmony between the composition of the higher forms of organization and that of the lower, upon which the higher live;—all this has been clearly exposed before; nowhere at such length and so well as in the Bridgewater treatises of Prout and Roget in especial. The thing is even most ably shown forth within much smaller compass, in the elegant lecture of M. Dumas, which appeared some years ago in French, under the title of more lately in English under the title "Leçon de Statique Chimique," and of an essay "On the Balance of Organic Nature."—But we would not be held censorious; we ought rather to quarrel with the managers of the Royal Institution for selecting chemistry as the subject of the Actonian prize essay, than with Mr. Fownes for having written a very sweet tract on the harmony that exists between the inorganic and organic realms of nature.

There is another and a delicate point upon which we shall adventure to touch in this place, and that is, the reception by a certain party in the church of this country, of all such essays as that of Mr. Fownes, and of all assistance which the naturalist ever pretends to supply to the theologian. We have oftener than once seen the anatomist brimful of the evidences of design and contrivance which he found in the structure of animals, but coolly listened to by the doctrinal divine, and finally flatly charged with deism because of his science and philosophy. The clergy as a body notoriously do not like medical men, whom they challenge as tinctured with scepticism in the mass. We for our own part have frequently regretted the woeful ignorance of physical science so conspicuous in the clergy at large. One of the high priests of nature, as we are, and intimately convinced that He who reveals his will in time, can be no other than the creator *of all things in eternity*, it has always

seemed to us that some considerable tincture of physical, and especially of physiological science, would be a vast ornament in the good divine, and would greatly help him in his understanding and appreciation of his brother the physician. But we quit this delicate subject, to state the cause of the appearance of this Essay of Mr. Fownes.

From his preface we learn that—"In the year 1838, Mrs. Hannah Acton, widow of the late Samuel Acton, Esq. of Euston Square, from motives of respect and regard for the memory of her deceased husband, and in order to carry into effect his desire and intention, caused an investment to be made of the sum of One Thousand Pounds in the three per cent. Consol. Bank Annuities, in the names of the trustees of the Royal Institution of Great Britain, the interest of which was to be devoted to the formation of a fund, out of which the sum of One Hundred Guineas was to be paid septennially, as a reward or prize to the person, who, in the judgment of the committee of managers for the time being of the Institution, should have been the author of the best essay illustrative of the wisdom and beneficence of the Almighty, in such department of science as the committee of managers should, in their discretion, have selected—the form and conditions of the essay being also, in great measure, left to the choice of that body.

"The subject chosen for the prize of the first period of seven years, was 'Chemistry, as exemplifying the wisdom and beneficence of God.' The prize was awarded in April last; and having, on this occasion, had the happiness to be the fortunate candidate, I now beg to offer to the notice of those who feel interested in such matters the essay in question, satisfied that my labour will not have been in vain if the smallest support drawn from the magnificent science of chemistry shall be found to have been given to the Great Argument."

This quotation will enable our readers to understand wherefore Mr. Fownes comes before us in the Actonian Essay. For our part we beg to recommend his well-written production to those among our readers who are not familiar with its subject. The book is elegantly printed and neatly bound, and would make a very appro-

priate, and, we should say, an interesting present to the youth of both sexes; upon a younger, or even an elder sister, who was either *seriously* or *not seriously* disposed, it would very certainly be well bestowed.

THE MEDICAL PROFESSION BILL —No. VI.

WHY ARE THE BILL AND ITS CONSEQUENCES
WHAT THEY APPEAR?

We have been greatly puzzled, like the vast majority of the profession, with the general tone and temper of this Bill, as well as with the nature of its immediate effects,—its first-fruits, as they may be called, the new Charter and the proceedings of the Royal College of Surgeons; the consequent alarm and dissatisfaction that have taken possession of the mind of the body of the general practitioners, members of the Royal College of Surgeons, resident in the metropolis, we can readily understand.

A certain party in the profession has been incessant for years in its cry for Medical Reform. We for our part never joined in the clamour: we saw room for amelioration, indeed, in several respects; but these we also saw in progress of gradual and safe development. We believed that we had the elements of improvement within ourselves, and as we were already constituted under various heads; we wanted not the rude interference of Government to drive us beyond our ability to keep pace with its behests; we desired not to run the risk of FOREIGN interference with our institutions, fearing that the effect of this might be to loosen rather

than to confirm the not overstrong bonds of good understanding that knit the discordant elements of the medical profession together, through wont and usage, at least, if not by absolute fitness.

We hope the reform party are pleased with the prospect that has been opened up to them;—stripped naked and fined by the minister—cast off and disowned by the Royal College of Surgeons—verily they have forced matters to a most prosperous conclusion!

We for our part have been greatly at a loss, as we said, to conceive the spirit that has actuated the movers or concoctors of this Medical Bill, its appendages included. We have been tempted to look beyond the "ignorant present," and our own limited circle in the metropolis, to the north and west especially, and we think we have at last arrived at a clue which may lead us to penetrate the mystery. In the first place, we do not hesitate to denounce the bill as *un-English* in its spirit, and as dictated by a feeling decidedly hostile to the general practitioners, members of the medical profession of this portion of the empire. Both Irish and Scotch influence, we feel morally convinced, have been at work to injure them; and so far the plot is full of promise. The Dublin College, for instance, hold themselves very high, and estimate their own members at a much greater price than the members of the London College. They have been known to declare that they had made no effort to raise the standard of the education and qualifications of the candidate for the diploma in surgery, that had not been frustrated and made nugatory by the system of underselling practised by the Royal College of Surgeons in London.

The people in Scotland, again, say that several of their graduates had been plucked, others prosecuted, and many more kept in fear of prosecution, by the Society of Apothecaries.

The authoritative surgical community of Ireland have, then, as we conceive, made a dash at the respectability of the members of the Royal College of Surgeons in London; the Scotch Universities, on their side, have made a dead set at the existence of the Apothecaries' Society, as a body, having weight or say in the education of the medical man, or the practice of medicine; and the College of Surgeons, we apprehend, have lent themselves to the two parties, to effect their several purposes. So far as we "can look into the seeds of time, and say which grain will grow and which will not," we see our own excellent Royal College playing every body's game rather than their own.

The circumstances upon which the Irish College ground their complaint of the London College are as bad as can be. In England we have many jobs, but in Ireland everything is a job; the constitution of the College of Surgeons of Ireland was one, of course. In their old charter no young man was admissible for examination for the diploma unless he had been bound apprentice to a member of the College; and the indenture could only be obtained upon payment of a good round sum, and doing the shabby work of the superior in the dissecting-room and hospital, as well as in private, for a long term of years. But comparatively few could afford either the apprentice fee, or the number of years of servitude which the indenture implied. The consequence of this was, that young Irishmen pursued their studies in Dublin for the two or three sessions required by the London College, at which no apprenticeship was necessary; and when furnished with the indispensable certificates, over they came to the Metropolis, presented themselves for examination at Lincoln's Inn Fields, and, smart fellows! *with the bones and muscles, arteries*

and nerves, at their fingers' ends, they passed as matter of course.

Now it is obvious that the examiners of the Royal College of Surgeons of London must have put large sums of money into their pockets, and into the College funds, by this means; and it is just as obvious that all they gained in this way was so much lost to the examiners of Dublin,—so much taken from their pockets and diverted from their common funds; the water that turned the London mill so briskly for many years, was in very large measure water taken from the Dublin mill-stream.

Our readers will understand after this, what is meant by the Dublin College of Surgeons, when they speak of their attempts to raise the character of the surgical profession having been frustrated by the underselling of the Royal College of Surgeons in London: the attempt to raise the character of the profession, rightly interpreted, signifies neither more nor less than this, that the selfish purpose of the Council of the Dublin College of Surgeons, in terms of their charter, to force large fees into their pockets by placing restrictive conditions of an onerous kind upon candidates for their diploma, was frustrated by the accessibility of the London College. A large proportion of the practitioners of Ireland are members of the Royal College of Surgeons in London; these men the magnates of the Dublin College hate and despise—it is their interest to humiliate them and make them feel their inferiority; hence the effort, so far successfully made, through the act of the College of Surgeons in London, to degrade these men, and along with them the body of general practitioners of England. Upon the other, but no less cogent grounds specified, will the hostility of the Scotch Universities and Colleges to the empire of the So-

ciety of Apothecaries be readily apprehended.

Our readers will now, we trust, understand wherefore Mr. Macaulay badgered Sir James Graham, night after night, about the Medical Bill until he was compelled reluctantly to produce it, and wherefore the *representative of the interests of Edinburgh and its University* gave his warm assent and support to the measure; we do not recollect whether any Irish member followed Mr. Macaulay in his approbation. We had not the light when the Bill was produced which we have now to enable us to read the motives of honourable members.

And now, having come to the conclusion at which we have arrived by a process of analysis and of synthesis, we venture very respectfully, but earnestly, to entreat the Council of the Royal College of Surgeons to reconsider the measures they have lately adopted, the steps they have lately taken. The numerous, the respectable body of men who constitute the members of the Royal College of Surgeons, cannot be left outcasts, degraded as they feel themselves to be by the arbitrary elevation over their heads, upon the score of no conceivable merit, of a certain number of their co-members. Almost to a man, the general practitioners of the metropolis have come to the conclusion that the pure surgeon and physician are in league to degrade them, and they are now animated towards both with bitter feelings of hostility and revenge. To have spared these feelings would have been worth large sacrifices. We do not say that the general practitioners are all that they might be in point of acquirement, &c.; still, we maintain that a more respectable body of men than the general practitioners of England, in life and morals, does not exist; they certainly surpass the clergy, who are our teachers of morals, and authorities in

religion. The profession of medicine has unquestionably a humanizing and an ennobling influence; he who is engaged in it, and has had an indifferent elementary education, soon becomes alive to the fact, and if his opportunities do not always, or, perhaps, even generally, enable him to do much in the way of repairing his deficiencies, still are they ever subjects of regret to him—he is never contentedly ignorant. And then, if these men be not all that is held desirable, whose is the blame? who prescribed the course they followed, the education they received? who tested their competency, and gave them their certificate of fitness? The Court of Examiners of the Royal College of Surgeons. It is their own offspring that they are condemning, their own act and deed that they are proclaiming to the world as unrighteously done. The medical education of the general practitioner, of him who is at once Member of the Royal College of Surgeons and Licentiate of the Society of Apothecaries, is actually better, more complete, than that of him who is member of the College alone; on the score of prescribed education the general practitioner has claims superior to the member of the College only.

MEETINGS OF THE PROFESSION UPON THE SUBJECT OF THE MEDICAL BILL.

SINCE our last several meetings have been held in connection with "our Bill." The first took place on Tuesday evening last, in the Council Chamber, Reading; Richard P. Smith, Esq. M.D. in the chair.

Meeting at Bath.

The purpose of the meeting, as stated by the Chairman, was to deliberate upon the nature of the Bill introduced by Sir Jas. Graham, entitled, "A Bill," &c., and to petition the two Houses of Parliament against the Bill as a whole.

Dr. Cowan moved the first resolution; and as we are well pleased to have the sentiments of a man so able

and so respectable as Dr. Cowan, on the Medical Bill, assuming them also to be in harmony with those of the medical profession generally in his neighbourhood, we make room for the abstract of his speech as given by the Reading Mercury of Saturday last.

Dr. Cowan commenced by observing that the object of the meeting was not to pronounce indiscriminate condemnation on the bill, which unquestionably contained certain clauses adapted materially to improve both the education and corporate interests of the medical profession, but to protest against that part of it which involved the removal of all restrictions upon unqualified practice. The appointment of a central controlling and representative body, or Council of Health and Education, was in itself a most desirable measure, though, as constituted in the bill, it could not otherwise be regarded than as too exclusively ministerial in character, and as failing to represent the opinions and interests of the medical profession. Still, the intention was good, and the proposal should be thankfully received. (Hear.) Another advantage of the bill was, securing an uniform and efficient standard of professional education, compelling all practitioners to give evidence of their qualifications, reducing the number of the licensing universities, and rejecting all foreign diplomas. These, with an improved system of registration, and the limiting all public appointments to regularly educated practitioners, could not be otherwise regarded than as great and important improvements; but notwithstanding such acknowledged benefits, it would be far better, he remarked, to leave the profession as it was, than to pass such a bill in its present form. The consequences of removing all restrictions upon unqualified practice would be most ruinous to the public, and most unjust to the profession. The legislative enactments now in force had materially contributed to diminish the numbers and encroachments of empirical pretenders. To repeal them, without the substitution of others in their stead, would be nothing better than a deliberate act of suicidal folly. Quackery, it was true, could never be destroyed by any legislative measures; but to assert that it could not be lessened and controlled by firm and consistent enactments, was at variance with all known experience, and contrary to the example of every other civilized community. England, with all her blessings, was worse provided for in her medical institutions, as regarded illegal practice, than any other European country; and while the bill was most properly insisting upon a high standard of qualification for the individuals who were entrusted with the responsible duties of

ministering to the public health, it presented the monstrous anomaly of providing no legal protection for those who had complied with its requirements, while it permitted the unrestricted competition of the ignorant and designing. The protection implied in public appointments and in registration was nugatory and ideal; and were the present measure permitted to become the law, the profession and the public would suffer to an incalculable extent. But not only was medical practice to be uncontrolled, but the present monstrous system of stamped and patent medicines remained untouched, and government still consented to profit by a commerce waged by ignorant and unprincipled men upon public ignorance and credulity. Stamps and patents were accorded, without even the shadow of inquiry, to every nostrum and statement, however injurious and absurd, and the population of this country was doubly deceived by a partnership between the government and the empiric. Such a state of things was at once a violation of common sense—a serious injury inflicted upon the governed, and an insult to a legally qualified profession. (Hear, hear.) That statement would not be thought exaggerated by those who were acquainted with the real evils of empiricism. Many hundreds, if not thousands, of lives were annually sacrificed from the want of well and easily adjusted legal restrictions, and an amount of injury inflicted upon the public health impossible to estimate. If qualified men were necessary, the unqualified were injurious; and to require that they be punished and restrained, was only consistent with what they owed to themselves and to the public.

The petition agreed to is as follows:—

The Petition of the undersigned Physicians, Surgeons, and Apothecaries of Reading and the surrounding districts,

Humbly sheweth,

That your Petitioners are legally qualified Practitioners of Medicine and Surgery, resident in Reading and its neighbourhood,

That they deplore the anomalous condition of the Medical Profession, and concur in the expediency of its revision by legislative enactment.

That although they regard with satisfaction some of the provisions contained in the projected Bill of Sir James Graham, yet, as a whole, they view it with a disappointment, disapprobation, and alarm; for while it professes to protect the Medical Profession, and the public health, they believe it to be directly and most grievously injurious to both.

That it offers direct encouragement to Empiricism, with its enormous and in-

calculable evils, tends to degrade the educated and legalized Practitioner, and to discourage and retard Medical Science.

That it is unjust to Practitioners who have qualified themselves by a prolonged and expensive course of study, to subject them to an open and unrestricted competition with the uneducated; and while protecting the Army and Navy, together with the poorer classes, it fails to provide for the great body of the community, and exposes them to the wrongs and miseries of the unprincipled pretender.

That the repeal of the Apothecaries' Act, without substituting ample security against Empiricism, is both unwise and unjust; and that any Bill which does not provide direct and efficient prohibition, will fail to give adequate protection to the Profession and the Community.

Meeting at Leeds.

On Thursday last, a numerous meeting of medical men, of the Borough of Leeds, took place at the Philosophical Hall, on the subject of "The Bill," Samuel Smith, Esq. in the Chair, from whose opening observations we are sorry to see that there is misunderstanding in the Leeds camp. Let all well-wishers to their common profession endeavour to cement differences at this juncture; "divide et impere" has hitherto been too sure a maxim to act upon in reference to the medical profession, and we shall grieve to see indications of division when nothing but unanimity can be of any avail. Mr. Smith, after explaining the object of the meeting, stated that the reason why the physicians, as a body, had not united with the other medical practitioners in the present proceedings, had arisen from some misunderstanding connected with the preliminary arrangements. Mr. Hey moved the first resolution, which he said was merely of an introductory character, expressing the desirableness of some measure of medical reform, and their satisfaction that Her Majesty's Government have become alive to the subject. Mr. Nunneley moved the next resolution, to the effect that the meeting viewed with satisfaction the approximation made towards a high and uniform standing of qualification for all members of the medical profession. He strongly urged the desirableness of a high and uniform standard of qualification for the medical profession, and pointed out many of the disadvantages which he conceived to result from the large number

of licensing bodies at present existing in the country, all possessing certain privileges, but having no uniformity of qualification, and many of them only conferring the right to practise in limited localities. He conceived the science of medicine and surgery was indivisible. He repudiated the existence of artificial distinctions in the profession, considering that no man was qualified to practise in any single division of the science, unless qualified to practise in the whole; and that the only distinction which ought to exist amongst medical men was that which was the result of superior ability or greater industry. He would have the government fix a high standard of examination; but having done that, he would have it interfere no farther, but leave those who had passed that ordeal to find their own standing in the profession. As to the bill which had been introduced, he thought it good in some respects, and that Sir James Graham was well-intentioned in the matter; he referred to the proposed Council of Health for the regulation of the different licensing bodies, as calculated in some measure to produce uniformity of examination. Speaking on the subject of quackery, he urged the necessity of protection both to the public and the profession; and observed that scores of individuals in this town had lost their lives from improper treatment by unqualified persons. He also instanced that within the last fortnight he had seen a person who had lost an eye, and he had no hesitation in saying that it was not put out by the disease, but by the druggist. Mr. Price proposed the next resolution, urging the government to adopt more stringent means for the suppression of quackery, against the inroads of which the government measure seemed to him to offer no sufficient protection. On the motion of Mr. Braithwaite, a permanent committee, to carry out the views and objects of the meeting, was appointed.

Meeting at Hereford.

A public meeting of the medical profession of the city and county of Hereford, was held at the General Infirmary in that city, on Monday, the 16th instant, to take into consideration the provisions of the new Medical Bill, to frame a petition against its objectionable points, and take such other steps

as might be deemed necessary to oppose them in the best and most efficient manner; Dr. Bleeck Lye in the chair.

Resolutions were carried to the effect—"That the members of the medical profession present at this meeting cannot but regard the provisions of the Medical Bill with feelings of disappointment and alarm; for while they allow that the establishment of a Council of Health, and an improved system of organization for the entire body of the profession, is much to be desired, yet they consider that many of the provisions by which these objects are proposed to be effected are liable to great objection, and that the repeal of all the existing protective enactments, without the substitution of others in their place, more than counterbalances any beneficial effects which such an improved system might be calculated to produce."

"That this meeting deprecates in the strongest manner possible that principle of the Bill which, by removing the stigma of illegality from empiricism, throws open the practice of medicine to every unqualified person, as a measure disastrous of the public welfare, and ruinous to the best interests of the profession."

We cannot make room for more of the resolutions; but they were generally such as the profession at large seem to approve. A petition was agreed on to Parliament, an association formed, and after the meeting, at the invitation of the gentlemen resident in Hereford, their medical brethren from the country dined with them at the City Arms Hotel, and the evening passed off most agreeably to all parties. This is all as it should be; we love to hear of medical men dining together; after all, there is nothing like temperate sociality for cementing good feeling.

ON THE NECESSITY
OF EFFECTING
EXCHANGES IN THE COUNTY
ASYLUMS

OF RECENT AND CURABLE CASES OF INSANITY FOR CHRONIC AND INCURABLE CASES*.

WERE a casual observer of the passing events of the day asked his opinion of

* Dr. Boyd's Report as to Lunatics, &c. chargeable to the Parish of St. Marylebone (Pamphlet, pp. 16).

the prevailing character of society, he might with justice remark, that the present generation is mostly conspicuous for the countenance it gives to the *exposure* of existing evils, without lifting so much as a finger for their remedy or removal; that it has an open ear for tales of misery, but a most tardy hand for relief.

This character of the age generates a mawkish spirit of philanthropy, which needs for its existence the stimulus of harrowing scenes of wretchedness. Of this, unfortunately, there is too great an abundance, and of men—interested men—too many to pander to the public taste. The wants and destitution of the poor afford a wide field for all that is requisite to keep up the delusions of the one class, or to gratify the personal vanity of the other; in the meanwhile, relief stops at the threshold, or remedies are suggested which are as fruitless to the poor as they are burdensome to the rich.

Year after year, and session after session, has this important national subject, the "Poor Laws," occupied public attention; and, in spite of all the display of senatorial oratory, statistics, and petitions, the land is still cursed with the most abject pauperism—the poor have asked for bread, and have received stones.

Lamentable as such things are, this is not the place for political controversy, and we must rely on the efforts of earnest but disinterested statesmen for their amendment.

There is, however, a subject in connection with the welfare of the poor which it is more in our province to notice—we allude to the management of the insane poor; and we may here observe, that if the remarks which we have made above in reference to the morbid sympathy towards the poor in general, be correct, much more do they obtain in the case of pauper lunatics, whose misfortunes and mismanagement have been made the medium of much notoriety to many a would-be philanthropist.

Without intending to be censorious, it is really painful to witness how this subject has been hawked before the *sympathetic* public—how fashionable it has become as a means to an end—as a topic wherewith to agitate the susceptible bosoms of the many, and to establish the reputation of an ambitious few. If good resulted from the exercise of such

evil means, the practice even then would be scarcely venial; but when, after all the vaunted benevolence, we learn that opposite results follow, it becomes highly reprehensible.

We would not be misunderstood: we heartily commend the exertion of many *really* benevolent men, whose lives have been devoted to the amelioration of the insane pauper; and we point to the results of their labour in the amount of cures effected, and the comparative happiness of the confirmed lunatic in a well-conducted establishment. We regret to find that this is not a universal state of things, and that, notwithstanding the "great cry" which has accompanied the annual reports of the Middlesex Asylum, that but "little wool" is the result. This is an unexpected and a disagreeable fact, which has just been revealed in a very temperate pamphlet by Dr. Boyd, of the St. Marylebone Infirmary. The simple statement of facts which pervades this unassuming pamphlet forms a striking contrast to the glowing and self-laudatory reports of more than one county asylum.

It would appear from Dr. Boyd's pamphlet, that since the year 1842 the propriety of exchanging incurable and quiet cases from the asylum at Hanwell, for the acute cases as they occur in the parish of St. Marylebone, has been urged upon the authorities at Hanwell, presuming that their establishment is more a *hospital* for the cure of the insane than an *asylum* for the incurable and harmless. This reasonable request has never been complied with, and on one occasion was *officially* declined by a committee of the visiting magistrates.

Impressed with the importance of procuring such an arrangement, the proposal has been made again and again, and urged in every point of view, but without effect, and in spite of the following facts, as expressed in the pamphlet — that "the early stage of insanity is that in which the greatest benefit is to be derived from the curative means obtained at so much cost in the Hanwell Asylum, and it is a gross act of injustice to the poor of this parish to have the beds in that asylum occupied by incurable cases, to the exclusion of recent cases yet in a curable state;" and again, that "there is not a single case now at Hanwell of less than a year's duration—a fact of considerable

importance, as much as statistics prove that after this period a continuation of the disease may be expected. There are about forty cases in private hospitals and in the infirmary, many of them of recent date, and a large number of deaths, whereas, in the county asylum, we are admitted to the County Asylum, by must in consequence be prevented from the very best chances of recovery."

Such reasons are expected to be well alone justify the exchange which Dr. Boyd advocates; but in order to remove all doubt upon the subject, he further adds:—"With the view of showing how inadequate the works of the Infirmary are for the curative treatment of the insane, it will suffice to quote but one instance, and which is of frequent occurrence, viz. the case of a convalescent by the introduction into the same ward of one or more acute and dangerous cases, the result of an effective means of separation, which can only be effected by a separate county asylum like Hanwell, which is constructed expressly for the purpose."

The above facts stated by Dr. Boyd are confirmed in the Report of the Metropolitan Commissioners in February 1846, page 87 of Report. "In reference to the population parish of St. Marylebone, the magistrates are inclined to exchange old incurable for recent and curable cases. But the problem, and indeed the main object of a county asylum, or ought to be, the cure of insanity. The patient, who had the benefit of a trial in the asylum where he had become incurable, we submit, giving up the affected pauper, who in the workshop, or at home, and is probably curable, and equally entitled to be received at the asylum, where, by prompt and proper treatment, he may be restored to health and to his family, instead of being permitted to become an incurable lunatic, a source of expense to others, and of suffering to himself. A county asylum is erected for the benefit of the whole county, and is to be considered not merely a place of reception or custody, but as a public hospital for cure. A large number of the patients now in Hanwell derive no substantial advantage from the means of cure and employment furnished in that asylum, and might be provided for in a separate establishment, thus making room for patients who are susceptible

of cure. The result of the system adopted by the Justices in Middlesex is, that the County Asylum is nearly filled with incurable lunatics, and almost all the recent cases are practically excluded from it. When we visited it in March last, there were 984 patients, *of whom only thirty were reported curable!* and there were 429 patients belonging to the county out of the asylum; and 40 applications for admissions had been refused within less than three months from the commencement of the year."

The above is a sad confirmation of our previous remark, that the distresses of the poor are more frequently discussed for purposes of display, than met in the true spirit of Christian charity. It is doubtless very gratifying and very moving to read of the deluded inmates of our County Asylum having balls, plays, &c. to remove the tedium of their existence; but we must not forget (however unpalatable the fact), that this act of supererogation is at the expense of protracted, and often of permanent, disease to many of their fellow sufferers.

Dr. Boyd's position, as the resident physician of an Infirmary of the most populous parish in the kingdom, must afford him ample means of ascertaining the most intimate wants of the poor; and we rejoice to find that, availing himself of these advantages, he has called the attention of the Board of Guardians to the important subject of their lunatics in a way the best calculated to engage their affections in behalf of these unfortunate beings. His appeal to the Guardians is confined to the *simple statement of facts*, which breathes more warmth and life into the subject, and enlists more *genuine* feeling in his cause, than all the garnish and touching anecdotes of Exeter Hall, or elsewhere, could possibly effect. In a word, we are pleased with Dr. Boyd's pamphlet, and heartily wish it "God-speed."

DEATHS FROM SMALL-POX.

A NUMBER of deaths from small-pox reported after vaccination, having occurred lately in the metropolis, a letter was addressed by the Registrar-General to the several metropolitan district registrars, requesting information upon the particular cases that were entered in such terms. The Registrar-

General submitted the following queries to the district officers. 1st. When was the vaccination performed? 2d. By whom was it performed, and was it seen afterwards, and did the medical man say that it had taken effect? 3d. Was there any mark left on the arm? 4th. State the name and address of the medical man who attended the patient in his last illness.

The answers to these queries having been duly received, they were forwarded to Dr. Gregory, Physician to the Small-pox Hospital, for his examination; and his conclusions in regard to them have been published from the General Register Office. Dr. Gregory says:

"I have carefully perused the details of 34 cases of small-pox proving fatal after alleged vaccination, which you have done me the honour to submit to me, and beg to offer the following short commentary upon them." He then goes over each case seriatim, and gives the following summary:—

Cases incorrectly registered	11
Cases too doubtful to be made matters of inquiry	8
Undoubted cases of fatal small-pox after vaccination, in the adult	5
Cases of small-pox fatal in early life after vaccination	10

Total 34

The deaths of five adults after vaccination afford no scope for special comment. Similar cases have been recorded in all countries for many years past. But the deaths of 10 children after vaccination is a new feature in the history of the disease, and therefore demands a special investigation.

"The ages of these ten children are as follows: 1 of 9 years, 1 of 8, 2 of 6, 1 of 5, 3 of 4, 1 of 3, 1 of six months.

"2. In all of these cases the evidence of prior vaccination was such as to justify the Registrar in recording them as cases of fatal small-pox after vaccination.

"3. These children were vaccinated in different localities, shewing that the source of the vaccine imperfection was not local."

"4. The respectability of the vaccinators, and the appearance of scars in eight of the recorded cases, forbid the assumption of entire irregularity in the vaccine process."

"5. How are these cases to be explained? Are we to suppose that the virus employed in these vaccinations was less energetic than that which was formerly in use; or is it that some change has taken place in the human constitution in the course of the last half century? It is unquestionable that such a series of cases occurring forty-four years ago would have had a material influence on the fate of vaccination. Now, with our am-

ple experience of the benefits of vaccination, the fear is lest these cases should fail to attract that attention which may lead to ulterior benefit.

"6. In reasoning on these cases, it should be borne in mind that they are the first of the kind which have been brought before the notice of medical men. Similar occurrences may have taken place, but they have attracted no attention either here or abroad. No corresponding cases have been recorded in any of the quarterly reports transmitted from the provincial registrars of England and Wales. Nothing parallel to them has occurred in the experience of the Small-pox Hospital. The earliest stage at which small-pox has there been observed to prove fatal is fourteen years, though several instances of the disease in a milder form have occurred at earlier dates.

"7. These considerations afford ground for supposing that lymph of an imperfect quality had been used in some, at least, of these instances. Whether this supposition be well or ill founded, whether it applies to the lymph now in use, or otherwise, may be doubted, but the occurrence of ten fatal cases among children in the metropolis in the short space of a few months demands the especial attention of all who are engaged in the practice of vaccination. It behoves them, as well for their own credit as for the credit of vaccination, to be extremely careful in the selection of vaccine lymph, and to be distrustful of the result wherever the course of the vaccine process has been irregular.

"8. These cases suggest the necessity of enforcing by law a medical certificate of the cause of death in every case of registry. With such a precaution, the irregularities in the register of deaths, already adverted to, never could have occurred. I feel assured that the medical profession throughout England would willingly cooperate in such a design if the legislature should think fit to ordain it.

"9. These cases further impress me with the great importance of restricting the number of those to whom the parochial system of vaccination (enjoined by the Vaccination Extension Act) is entrusted. I speak after twenty-two years' experience in the practice of vaccination; and I know that the choice of effective lymph requires much tact and discrimination, and that, except at vaccine stations, where considerable numbers congregate, such choice cannot be had, nor such knowledge acquired."

In the letter to Dr. Gregory, with which Mr. Farr, of the General Register Office, accompanied the returns from the district Registrars, that gentleman put several very pertinent queries, which, with Dr. Gregory's answers, are as follows:—

"1. In what proportion of cases does vaccination duly performed with fresh lymph fail to produce cow-pox?—When lymph of adequate purity and intensity is used, the proportion is so small as scarcely to merit notice. Not more, certainly, than 1 in 1000 cases.

"2. Have persons in whom cow-pox cannot be induced by inoculation any unusual immunity from small-pox? To what extent does that immunity extend?—The few persons who are really insensible to cow-pox are believed to be insensible to small-pox also, but the subject is little known, and in the present state of the law, prohibiting inoculation *even for the purposes of scientific investigation*, not likely to be better understood.

"3. Are persons who have been vaccinated without effect to be considered 'unprotected'?—Persons who have been vaccinated without effect are in all cases to be considered as 'unprotected,' because the chances are that the want of result is attributable to the vaccinator, and not to any peculiarity in the person operated upon.

"4. Have you any means of knowing the proportion of persons in the metropolis

- (a) Who have never been vaccinated?
- (b) Who have been vaccinated without effect, or without leaving cicatrices?
- (c) Who have had cow-pox?
- (d) Who have had small-pox?

—No means exist for ascertaining the proportion of persons resident in the metropolis who have been subjected to vaccination—still less to determine what proportion of the vaccinated have undergone that process normally or only nominally. All persons above the age of 44 may reasonably be supposed to have undergone inoculation rather than vaccination, but even this attempt to classify the metropolitan population with reference to small-pox and its antidote, is obviously open to numerous objections.

"5. What is the relative mortality of small-pox (natural)—and small-pox after cow-pox?—The mortality of small-pox in the unprotected exceeds 1 in 4, and hardly reaches 1 in 3. It exceeds 25 per cent., but scarcely amounts to 33. We may state 30 per cent. as the average. The mortality by small-pox as it occurs among the vaccinated is 10 per cent. As the numbers admitted into the Small-pox Hospital, vaccinated and unvaccinated, are now nearly equal, so out of every 200 cases, we have one-half yielding 30 deaths, the other half 10 deaths; total 46 deaths out of every 200 cases, or 20 per cent. *mixed cases*, which is our present rate of mortality."

REPORTS,
 BY H. FEARNSIDE, M.B.,
 OF
 CASES TREATED IN UNIVERSITY
 COLLEGE HOSPITAL.

[Continued from p. 723.]

REMARKS.—The most prominent symptoms in this case were at once calculated to direct the attention to the heart as the organ principally affected; and the slightest inspection of the patient's chest not only confirmed the supposition of the existence of disease of the heart, but disclosed the fact that it was of great extent. The impulse of the heart, as well as the dulness on percussion, was perceptible over a much greater extent of surface than in health. This fact also served to point out that the heart was dilated as well as hypertrophied; and the smart but strong impulse of the organ exemplified the characters which the impulse usually has in this form of cardiac disease. From the impulse being perceptible in the epigastrium as well as to the right of the sternum, and from the dulness on percussion over the lower part of that bone, and even for some distance to its right, it was clear that the disease was not confined to the left side of the heart.

There was also evidence of the existence of valvular disease, in the morbid character of the first sound of the heart in particular, and the situation in which the murmur was most audible (over the site of the apex), indicated its being produced in the mitral orifice. But there appeared to be more than simple regurgitation of blood into the left auricle, as was shown by the prolongation of the murmur upon the second sound, the indistinctness of this sound opposite the apex of the heart, and the slight murmur sometimes succeeding it. These phenomena must have depended upon some current *into* the ventricle; but that this was not owing to regurgitation taking place through the aortic orifice, was proved by the distinctness with which the natural second sound was heard over the base of the heart, and by the absence of any morbid sound in the blood-vessels. Hence, as Dr. Williams observed, it appeared most probable that the morbid character of the second sound was owing to obstruction to the passage of the blood from the left auricle into the ventricle. Obstructive mitral murmurs are certainly exceedingly rare; the force of the current from the auricle to the ventricle being rarely sufficient to give rise to the production of sound. It is conceivable, however, that they may exist under certain

circumstances, as where the left ventricle possesses considerable diastolic elasticity; or where, from long-continued regurgitation into the left auricle, this compartment of the heart is not only dilated, but excited to continually increased action,—and when, at the same time, a considerable part of the surface of the heart is brought into contact, at each pulsation, with the walls of the chest. With a concurrence of the conditions indicated, if obstruction exist to the passage of the blood, and especially if this be of a nature to be easily thrown into vibration, the production of a morbid sound is only what might have been anticipated. Again, in some cases the union of the segments of the mitral valves, at their contiguous margins, renders them incapable of performing their valvular office, and they present an infundibular projection into the cavity of the ventricle: now, if the margins of the aperture thus formed are free to vibrate, and the other conditions mentioned exist, the occurrence of a murmur would be intelligible, and especially when the heart was not acting very strongly, and the quantity of blood expelled at each contraction of the auricle was considerable.—*Dr. Williams.*

The pulse in this case had much of the irregularity and inequality characteristic of mitral disease. On some occasions, when the heart was acting with much violence, not more than half of its pulsations were transmitted to the artery at the wrist.

Regurgitation into the left auricle, by distending this cavity, and impeding the free discharge of blood by the pulmonary veins, has much tendency to produce pulmonary congestion;—this existed to a considerable extent at various times in the progress of the case, and was evidenced by the dulness on percussion over the postero-inferior parts of the chest, the muco-crepitant rhonchus, the cough and dyspnoea; the latter being especially distressing at night, when respiration is completely an "excited" act, and when pulmonary congestion is also favoured by the recumbent posture; respiration must also have been interfered with by the encroachment of the greatly enlarged heart upon the pulmonary tissue, thus diminishing the available part of the respiratory apparatus.

The disease of the heart produced very decided effects upon the brain and organs of the senses;—these were obvious in the disturbed sleep, frightful dreams, headache, and giddiness;—these symptoms clearly indicated a disordered state of the cerebral circulation,—and to the same cause might be referred the affection of the organs of vision and hearing.

Various disorders were manifested in the state of the abdominal viscera: the stomach

had suffered,—the patient frequently had anorexia, nausea, and vomiting; the liver was somewhat enlarged; the bowels were irregular, and the catamenia had been absent for a considerable time. The kidneys did not appear to have been implicated to any extent at the time of the patient's admission, but after the febrile attack, the urine became albuminous, and continued so to the time of the patient's death. If granular degeneration of the kidney be connected as a result with disease of the heart, we should certainly expect its development in such an instance as the present, where the latter was so extreme. The large excess in which urea, lithic acid, and its compounds, existed in the urine at various times, is worthy of observation, considering the little waste of material which must have been taking place in the system, except in the central organ of the circulation itself. Our acquaintance with vital chemistry is still too imperfect to explain this,—but we might almost be led to suppose that there existed some vice of conformation, leading to the undue development of lactic, or lithic acid, urea, &c. Such supposition might also explain the unusual disposition to rheumatism.

The cause of the heart-disease in this case was in all probability rheumatism; we find that the patient had never had palpitation, or any other symptom of disease of the heart, before her second attack of rheumatism; and since that period the evidence of its existence had been unequivocal. The heart is peculiarly liable to suffer in rheumatic attacks, by an extension of the inflammation to it, on account of the large quantity of fibrous tissue in its composition, and in that of its investing membrane;—also from its perpetual motion, and being necessarily so liable to be influenced by changes in the character of the blood. But there would appear to have been a peculiar tendency to disease of the heart, as well as rheumatism, in this case, probably depending upon original constitution; and this view is supported by the fact that a young brother of the patient, who had never had rheumatism, also, suffered from cardiac disease;—the affection however does not seem to have been hereditary.

The *prognosis* in this case was very unfavourable;—the extent of the disease was so great, that unless it had been slowly developed, life could not have been maintained. For a considerable time the state of the system generally appeared less impaired than might have been expected; there was but little emaciation, and the process of sanguification did not materially suffer, and on this ground must be explained the late appearance of dropsy. Imperfect action of the excreting organs, indicated by a constantly albuminous state of the urine,

was the prelude of dropsy, and a general failure of the powers of the system.

The indications of *Treatment* were to moderate the excessive action of the heart, and remove any local congestions which it might occasion; to act upon the excreting organs; and support the strength of the system. The means by which it was attempted to attain these objects have already been mentioned, and nothing more need be said upon the subject, except that the efficacy of the measures, and the influence of quietude and repose, were strikingly seen at various times in the progress of the case; showing that most important relief may be afforded in very extreme cases of disease of the heart.

VAGINA AND NECK OF THE UTERUS DOUBLE;

SECTION OF THE VAGINAL SEPTUM,
DELIVERY BY THE FORCEPS.

By M. LESAING.

THE anomaly presented by this case has seldom been witnessed under such interesting circumstances, and the modified operation of the division of the septum is worthy attention.

M. Lesaing was sent for by the medical man in attendance, to a woman 36 years of age, who had been in labour two days with her first child, because he could not discover the os uteri. M. Lesaing, having introduced his finger, could not perceive at first any approach to the natural formation. After some time, however, he discovered between the labia and the nymphæ on the left side, as high up as the meatus urinarius, an opening which communicated with a large space, where he felt the head of the foetus, and the neck of the uterus. Pushing his finger forwards he enlarged this opening, and felt near the neck a communication with a second vagina which had been first examined both by himself and the other medical attendant. The two canals were completely separated by a very thin septum from eight to nine centimeters in height. The neck of the uterus was continuous with that vagina which could not admit the passage of the head, whilst the one which corresponded to the well formed vulva terminated in a cul-de-sac. But at the end of the septum, close to the neck, there was a small opening, through which the semen had most probably found access to the womb.

The weakness of the woman, the time she had been in labour, and the discharge of some yellowish water at each pain, showed there was no time to lose. M. Lesaing determined to divide the septum, after

having tied it to prevent hæmorrhage, which was effected in the following manner. He twisted round the point of his index finger the end of a waxed thread, which he introduced close up to the neck of the uterus, where he felt the lateral fissure of the septum, which he crossed by bending his finger; then turning its point towards the external opening, he seized the thread with the fingers of his other hand: he tied the thread firmly one centimeter below the meatus urinarus. A second thread was passed in the same way, and tied as near as possible to the perineum, thus leaving between the two ligatures an interval of half a centimeter for the division of the septum. The fore finger was then slipped behind the membrane, which M. Lesaing divided with scissors on the point of his finger, which he introduced as far as the neck.

One hour having elapsed without any progress in the labour, recourse was had to the forceps, and the woman was delivered of a living but weakly child. The cure was complete on the twentieth day. At this period M. Lesaing examined per vaginam, and found two openings near each other, united together by a thin membrane anterior to the rent he made at the time of the labour. The neck on the right is smaller than that on the left side, and situated more posteriorly. They are so placed that after the finger is introduced into one opening the other is not perceived by the side of it. The uterus is single.—*Gazette Médicale*, Sept. 7, 1844.

CASE OF POLYPUS OF THE UTERUS

ADHERENT TO THE PLACENTA,
SUCCESSFULLY REMOVED.

By M. AUBINAIS.

A WOMAN, ætat. 35, was afflicted, after two natural deliveries, with frequent floodings, accompanied with pains in the loins. This state continued for five years, when she became pregnant a third time. When M. Aubinais was called to her, he found that the fœtus was expelled, the cord broken, and the placenta retained in the uterus. The insertion of the cord into the centre of the placenta was felt by the finger passed along it; but at twenty-seven millimeters to the left of its point of insertion, the presence of a tumor of the size of a large hen's egg was discovered, which made the placenta swell out into the shape of the bottom of a lamp. The placenta was detached from left to right, and the polypus was found to adhere to it, which explained the rupture of the cord. When the placenta was pulled, the polypus was drawn with it, as well as the uterus.

M. Aubinais firmly supported the uterus with one hand on the hypogastrium, then seizing the polypus, which appeared to him to have an elongated pedicle, he twisted it, and brought it away without much difficulty. The entire placenta came away with the polypus, and without much hæmorrhage. The adhesions of the polypus to the placenta were examined, and found to be strong, particularly over a space of the size of a franc piece. Several very small vessels had kept up the circulation between the polypus and the placenta, and on pressing these bodies at the same time, these vessels were seen to fill with blood. The patient was soon cured, and she has since been confined, making her fourth time, without any untoward symptom.—*Gazette Médicale*, September 7th, 1844.

LECTURES
ON THE
NATURE AND TREATMENT OF
DEFORMITIES,

*Delivered at the Orthopædic Institution,
Bloomsbury Square.*

By R. W. TAMPLIN, F.R.C.S.E.
Surgeon to the Institution.

TALIPES VARUS—continued.

THE treatment, which we now come to consider, gentlemen, resolves itself into the mechanical solely, or surgical and mechanical combined. With regard to the mechanical, I think sufficient evidence is daily before us of its general failure, from the results witnessed of patients who have been subjected to stretching and rubbing, and the wearing of instruments all their lives; and the existence of this institution is an evidence of its general inutility. I have not much, therefore, to say upon this head. It will undoubtedly reduce the severity of the appearance of the deformity, and may, in the slightest amount of contraction, perhaps effect a cure,—at least we are told it does so. I can only say, I have tried it both in congenital and also in non-congenital cases, when the deformity has been slight, and the contraction of the muscles very limited, but I cannot bear testimony to its success on the one hand, or the propriety of it on the other. I have no doubt it is a very profitable method of treatment, for under the most favourable circumstances it must be of long duration. Therefore, both to the attendant and the mechanist, it is thus far successful: but it is not for the pecuniary benefit of those who would ascertain the best method of making the most of their patients, that I am giving you my ideas upon this subject. The horrors of an operation are also removed, which, to the patient who can know nothing about it, are not insignificant; the very idea of the knife is to many an insur-

mountable objection. Therefore, in these instances, mechanical treatment is the most satisfactory to the patient, and should apparent improvement be observed, they will be perfectly content, which is sure to be the case, as no case presents itself in infancy that cannot be much improved in appearance by the hand alone, but I have not seen a perfect cure by mechanical means, although I have heard of it. The deformity in infants, as I have endeavoured to prove to you, is the result of, and maintained by, the action of the muscles alone; it is obvious, therefore, that the more speedy and easy the method of cure, and the less painful it is to the patient, the better; the motto "*cito tuto et jecunde*" must apply here, as well as to every other disease we are called upon to treat. If, then, the division of the contracted muscles will effect this, there can be no question of its importance, of its necessity. The next question is, what is the most favourable time for the patient—in the early months of infancy, or at a later period? I know it is, and has been, recommended to postpone it until the period at which the child would be expected to walk, and to endeavour to abduct the foot by the constant application of splints up to that time. My opinion, however, is, that if it be necessary to perform the operation, the sooner it is done the better; for it must, I think, be evident that a great advantage must be gained by the patient, as the foot of necessity will grow in the position in which it is placed. It must, I think, be admitted that the growth in the natural position is far preferable to the growth in the deformed position, both as regards the muscles and the ligaments of the joints. And again, in infants of a few weeks old you have no additional irritation to contend with, and the foot becomes placed in its proper position previous to the irritation of teething, or to the numerous ills to which children are subject. The maintaining the foot in position at this early period, after the contraction has been overcome, is a matter which occasions

no pain or inconvenience, with the most ordinary attention; much less than the constant confinement in a splint, with the muscles resisting. Again, if proper care be taken, the development of the muscles become thus naturalised, and the diminished development consequent upon their passive condition, even in infants, is prevented. Thus in every point of view it appears to me to be decidedly preferable to operate at the earliest opportunity. I have frequently performed the operation on infants of not more than five weeks of age, and should always recommend it to be done at this early age when opportunity offers.

The muscles whose tendons you will find it necessary to divide in every confirmed case of talipes varus, are, as you may have already anticipated, the anterior tibial, posterior tibial, gastrocnemius, and when the plantar fascia is contracted (decidedly), it will be as well to divide that also. The posterior tibial is the first muscle I would advise you to divide, inasmuch as the gastrocnemius assists to hold the foot firmly. The method I have adopted is the following:—let the child be laid horizontally on its back, and let the leg to be operated upon be everted so that you have the inner side facing directly upwards; you thus have the tendon directly before you: you will then feel for the tendon, which in a thin child can easily be felt to rise under the finger, upon any attempt to abduct the foot. In a fat child, however, you will not be able to do so, for you must recollect it is the edge of the tendon which presents itself, and not the flat surface. The guide I then find successful is the internal edge of the tibia (which can at all times be felt with more or less pressure), and the tendon, as you are aware, lies directly behind it, and close to it. Having, then, the foot and leg firmly held by an assistant, you place the thumb of the left hand on the edge of the tibia, or close to it; you then with a small scalpel puncture the fascia by passing it perpendicularly down, and with care, or you pass the instrument too far, and puncture the artery. But if you do it slowly and cautiously, you will be enabled by a sort of grating sensation to feel the fascia, in which you make a small slit; you then withdraw the scalpel, and introduce the blunt-pointed knife in a perpendicular direction also, or you will get on the tibia on one side, behind the tendon on the other, from its close approximation to the bone. As soon as you have got the knife before the muscle, or what you imagine to be so, depress the handle, and satisfy yourself, by the resistance, that it is so: having done this, turn the sharp edge to the muscle, and divide it, directing the assistant at the same time to forcibly abduct the foot. You are aware that the artery lies very near to the posterior tibial and flexor digitorum muscle,

and if you do not exercise great caution and judgment as to the distance, you may divide that also, which it is prudent to avoid: although at present we have seen no ill effects from complete division of the artery, yet we are not to imagine that such will be always the case. You may form some idea of the proper distance by letting the knife touch the edge of the tibia first, then pass it on-wards about a quarter of an inch, and divide the muscle. You must recollect that in infants muscular fibre exists almost down to the internal malleolus, so that the division will not give so sudden a sensation as of the division of tendon alone; but in all cases, I am confident, if the muscle is divided, the sensation must be communicated to the hand of the assistant. After having divided this muscle, place a piece of lint on the point of puncture, and keep the finger on it, and then proceed to divide the anterior tibial. This tendon you will generally be enabled to feel as it passes over the joint on the inner side, but in fat children you will experience great difficulty in finding it. It is better for you to satisfy yourself, previous to introducing the knife, of its position, as it is then done with the greatest facility. Having found the tendon, you place the fore-finger on it, and introduce a sharp-pointed knife under it; the assistant at the same time abducting the foot, as in the other instance. Let a piece of lint be applied, and the child turned on its face, so that you may have the tendo-Achilles directly before you. Here I would beg to caution you as to the position of this tendon, as you will not find it in the median line, as in the normal position of the foot, but considerably inclining to the inner side, lying directly over the vessels and posterior tibial tendon; and although with care you will find it easy to divide, yet care is requisite or you will transfix it on the one hand, or, by puncturing a little too deeply, puncture the posterior tibial artery on the other, which latter accident has actually happened. The manner of dividing it is the same as I detailed to you in my former lecture.

Having, then, divided these three muscles, you apply lint and strapping, and support the foot with a bandage; this you will allow to remain for three or four days, or until the punctures are healed. You then apply your mechanical apparatus—either Scarpa's shoe, or a common tin splint in infants, having one side piece, but extending only to the ankle, protecting the heel from pressure by padding the leg just above the os calcis, then strapping the splint to the leg, and leaving the foot free; the abduction may be easily effected with a small bandage passing round the anterior portion of the foot and splint, gradually bringing the foot to the splint, and, when the abduction is com-

plete, by bending the splint gradually, you may flex it. This plan I have frequently followed with complete success. If with Scarpa's shoe, first abduct the foot gradually, taking care the child is not in pain, and that there is no undue pressure. After the abduction, proceed gradually with the flexion, as in talipes equinus (which, in fact, it will then become), until it is bent beyond a right angle. You must then direct the mother how to apply the instrument, and let her take it off once or twice daily, with a view of exercising, with her hand, the motion of the joint. But do not allow this until all firm resistance is overcome, or you will find that the foot will almost invariably relapse to its former position. The time occupied will vary, according to the rigidity and severity of the case, from fourteen days to six weeks or two months; but you ought certainly to get it in position by that time, unless there has been any casual interruption to the treatment. In youth and adult deformity you will proceed in the same way with the operation, but as there is no superfluous fat you will be enabled to feel the posterior tibial tendon with ease; as oftentimes, by directing the patient to adduct his foot, a portion of the tendon rises above the bone. The anterior tibial tendon and the tendo-Achilles are also well defined, so that the operation is greatly simplified.

Other methods have been adopted in dividing the tibialis posticus—1st, that of passing a sharp-pointed knife behind and beyond the tendon, and then cutting directly onwards or inwards, according to the position of the leg. But by this method you run the risk of puncturing the artery, and of breaking the point of the knife in the bone, which I have seen done; whereas, in the method I have adopted, you do not disturb the integrity of the sheath or periosteum, except at the point of puncture, and thus avoid adhesion between the new uniting medium and periosteum.

In these cases, when the patient has walked for a greater or less number of years on the dorsum of the foot, where the ligaments of the foot have become contracted, and offer a firm dense resistance, you will find it impossible to proceed quickly. You will first, by a straight splint, abduct the foot, and, if in the adult, divide only the anterior and posterior tibial and plantar fascia at the first operation, with or without the flexor longus pollicis; and after you have abducted the foot, divide the tendo-Achilles, and proceed with the flexion. The reason for dividing the whole at one operation, in the infant, is, the short time occupied in abducting the foot, so that time is not allowed for the new uniting medium to offer any resistance; whereas, in the adult and youth, the time occupied in abducting the foot is sufficient to

enable the new substance to become firm, and offer as much resistance, or nearly so, as before the operation. In dividing the plantar fascia I would advise you to be cautious, and not to insert the point of the knife too deeply, as you may puncture either of the plantar arteries: should you do so, you may be compelled to take it up.

A boy of about sixteen years old, whom I assisted to operate upon, had the internal plantar artery punctured. Compression was kept up for weeks, at the end of which time it appeared to have completely healed. This lad afterwards came under my own immediate care. The extension was then commenced, and continued for three weeks, at the end of which time a lump was noticed on the sole of the foot. On carefully examining it, with my friend Mr. Ormerod, we could detect no pulsation, and decided upon laying it open. Upon introducing the lancet, clots of blood escaped to the amount of two or three ounces: I made a crucial incision, and cleared the whole out. I then placed a firm compress on the sole, and kept it fixed by strapping and bandages, and sent him at once to bed, keeping the foot raised by means of a pillow. For three days all appeared going on favourably. On the third day, however, the nurse sent round in a great hurry to say the boy was bleeding. When I arrived I found the bleeding stopped, and thought it possible it might be a discharge of blood and matter. However, on the following morning, it again returned, and evidently was pure arterial blood. I then called Mr. Lawrence in consultation. He agreed that it would not be prudent to delay the attempt to take up the artery. In the afternoon, with his most kind assistance, I laid open the sac freely, and found the sole of the foot full of clots of blood, matter, and shreds; on removing which, the artery was seen to bleed freely. A ligature was then passed under it by means of the needle, and tied, which effectually controlled the hæmorrhage. The boy felt a twitching pain, which was allayed by opium, and, much to my surprise, not a bad symptom followed. The ligature, however, has not as yet come away, eight or nine weeks now since the operation. But a more troublesome or difficult operation cannot well be imagined. You will therefore see the necessity of being cautious. This, I must observe, is the sole instance of this accident that has ever occurred, but it is sufficient to teach us a useful practical lesson. Compression on the posterior tibial artery did not control the bleeding in the least; compression on the anterior and posterior, however, did control it to a great extent, but not completely, so that we had no alternative but to take up the artery as I have before described to you.

The time occupied in treating a bad case

of talipes varus will vary from two to six, eight, or ten months, as it is impossible to overcome recontracted tissues, except by the most slow and cautious proceeding, and it will require the greatest vigilance to prevent a slough on the points of pressure. After you have abducted and flexed the foot, you will frequently find, as I pointed out to you, the tarsal extremity of the fifth metatarsal bone projecting considerably, so much so, that the weight of the body is thrown completely upon it, rendering it impossible for the patient to walk without some protection. I have used and found a spring pad, similar to a truss, well applied, raise it sufficiently to prevent any inconvenience, the one passing on the inner side, and upon the under surface of the fifth metatarsal bone, the other on the upper surface of the first and second metatarsal bones, and which, by the constant pressure of the spring, gradually reduces the arch of the foot, and raises the fifth metatarsal to a level with the sole. But this, I must tell you, is a tedious proceeding, and so, in fact, is the whole process. After the foot is in position, you will order a boot and support to be worn until the ligaments have gained strength in their new position, and also order the patient to flex and extend the foot night and morning. The cure in these cases depends on the restoration of the balance of power, especially in infants. You cannot fail to have observed that the peronei have become weakened from their having been kept constantly on the stretch; and immediately after the foot is brought into position, it cannot be expected that these muscles will be enabled to keep the foot in its proper position; you must never, therefore, allow the foot to be without the instrument, or boot and support, night or day, until sufficient power is attained by the muscles to keep the foot in position; as, should you do so, the cicatrix will not only have drawn the two ends of tendon together, but the anterior and posterior tibial muscles will regain the preponderance of power, and render it impossible for the peronei to recover themselves. This applies more particularly to infants and young subjects, as it cannot be expected that perfect motion can be recovered in complete varus of the adult, although they always possess limited motion. It is not necessary to interfere with the usual diet of the patient, either immediately following the operation, or at any time afterwards, but it is as well to guard against children taking indigestible food, as you may have suppuration and erratic erysipelas set up after the wound has healed, as in the following case.

About three years since I operated upon a child two years of age, for this deformity, and divided the tibialis posticus by making an incision and taking up the tendon on

the director. The wounds healed by the first intention, and everything proceeded favourably until the ninth day, when, to my great surprise, I found the parts surrounding the points of incision swollen, red, and painful. The instrument was left off, cold lotion was applied, and purgatives with liq. antimonii tartarizati, was administered. On the following day the inflammation extended as high as the knee, and the leg became cedematous. The inflammation continued to increase the two following days, until the redness extended as high as the anterior superior spinous process of the ileum. The purgatives were continued, and on the fifth day balls of currants were passed; from which time the erratic erysipelas subsided immediately.

This case excited a great deal of uneasiness, as you may suppose; but it gave good practical experience on the important point of totally forbidding any kind of indigestible articles of food to be given to the patient during the early period of treatment.

ON THE
PHYSIOLOGICAL CHEMISTRY OF
PROTEINE AND ITS COMPOUNDS.*

BY PROFESSOR MULDER, OF UTRECHT.

Translated from the Dutch,

BY JAMES PAGET,

Lecturer on Physiology, &c., at St. Bartholomew's Hospital.

(For the Medical Gazette.)

[Concluded from p. 827.]

THE mode in which the sulphur and phosphorus are combined with the proteine, in the compounds above mentioned, is not yet known. But it is known that the combinations are constant. And hence it must be true, that, in them all (and, for an example, in fibrine), either there is combined with twenty atoms of proteine a small quantity of a substance composed of one equivalent of phosphorus and two equivalents of sulphur, or, really Ph S are combined with ten atoms of proteine. In both theories there is a considerable deviation from what we are accustomed to observe in most inorganic compounds, and we are therefore justified in considering, for the present, the simplest of the two to be the true one; that is, that Ph S are combined with ten of proteine. This peculiarity, however, does not stand alone, for one

* From the "Proeve eener Algemeene Physiologische Scheikunde," door G. J. Mulder, Hoogleraar te Utrecht. St. IV. pp. 312-344.

equivalent of alum has 24 equivalents of water of crystallization.

It cannot affect the question, whether proteine as such is combined with Ph S, or whether its constituents divide Ph and S among themselves: proteine is, like amygdaline, a complex substance, consisting of various others, and such a partition of Ph and S among its constituents is therefore probable; but it is settled, first, that proteine can exist without sulphur and phosphorus; and secondly, that there are compounds in which 10 atoms of proteine are combined with Ph S, others with Ph S₂, and again, others in which 10 and 15 atoms of proteine are combined with S. Those at present known, for example, are the following:—

Crystalline . . .	15	Proteine + S
Caseine . . .	10 . . .	+ S
Vegetable gluten . . .	10 . . .	+ S ₂
Fibrine . . .	10 . . .	+ S Ph
Albumen of hens' eggs . . .	10 . . .	+ S Ph
Albumen of serum . . .	10 . . .	+ S ₂ Ph.

The combinations into which phosphoro-sulpho-proteine, or sulpho-proteine, can enter with acids, bases, and salts, or into which proteine can enter with oxygen, are important. With regard to the latter, two are known; one prepared from a chlorite of proteine by the action of ammonia, by which hydrochlorate of ammonia is formed, and, at the same time, a substance called tri-oxy-proteine (or tritoxide of proteine) is produced. It is also obtained by boiling fibrine and albumen in water, and is a chief constituent of the buffy coat of inflammatory blood. It is always found in small quantity in the blood, and is prepared in the lungs. Its formula is—

The second compound of proteine with oxygen is obtained from the preceding, by dissolving it in potash, and precipitating by an acid. The first precipitate obtained is proteine; the second, bi-oxy-proteine (or binoxyde of proteine)—

The sulphur of the hair (= 2 equivalents) combines with the potassium of a solution of potash in which hair is digested, and sets free a corresponding proportion of oxygen, which unites with the proteine, and raises O₁₂ to O₁₄, while all the other elements remain the same; then, in precipitating

the bi-oxy-proteine from the sulphuretted alkaline solution, water is decomposed, and sulphuretted hydrogen is given off: H₂ combines with S₂, and O with Ka₂; so that from 2 (Ka S) and 2 (H₂ O) there are formed 2 (H₂ S) and 2 (Ka O).

These oxygen-compounds of proteine are important bodies. They may be alternately formed and decomposed in the animal body. Scherer found that moist fibrine, exposed to oxygen gas, absorbs more oxygen than it gives off carbonic acid. It was therefore possible that an oxygen compound of proteine was here formed; and this has lately been proved to be the case. Fibrine boiled in water leaves bi-oxy-proteine undissolved, and tri-oxy-proteine is found in the water.

The chlorite of proteine, obtained with decomposition of water, from albumen, &c. when chlorine is passed through the solution, has for its formula C₄₀ H₈₂ N₁₀ O₁₂ + Cl₂ O₂, and is of such definite composition that the equivalent of proteine may be accurately deduced from it. It is entirely analogous in composition with sulpho-proteic acid. This compound does not occur in the body, but it is important in the art of bleaching, in the disinfecting of animal matter by chlorine, in the application of chlorine in medicine, &c. That this chlorite is really a chlorite of proteine, and not a chloride of tri-oxy-proteine, is certain, from its analogy with a corresponding compound of gelatine.*

The compounds of sulphur, phosphorus, and proteine (fibrine and albumen), and those of sulphur and proteine (caseine), with alkalies, acids, and salts, are especially remarkable. Proteine is soluble in weak alkalies. Now, the serum of the blood is always slightly alkaline; it is a proteate (with sulphur and phosphorus) of soda†, and thus

* That compound is here alluded to which is obtained after drying the precipitate obtained by passing chlorine through a solution of gelatine: its formula is—

$$4(C_{12} H_{20} N_4 O_8) + Cl_2 O_2. — J. P.$$

† This is rendered very improbable by the recent experiments of Enderlin at the Giessen Laboratory (Annalen der Chemie und Pharmacie, April und Mai, 1844). He says, that both the ashes of the blood, and the precipitates which are obtained from aqueous solutions of them by nitrate of silver and chloride of calcium, will dissolve in acids *without giving off any gas*: and that aqueous solutions of the ashes, though strongly alkaline, may be neutralized by the addition of neutral chloride of calcium. It is

holds sulpho-phospho-proteine in solution. On this property depends the maintenance of the fluidity of the blood, and, thence, a first requisite of animal life. If a weak alkaline solution of proteine be neutralized with an acid, the solubility of the proteine with sulphur and phosphorus is greatly diminished; and this may illustrate the medical action of some acids, such as the sulphuric and phosphoric, which are well-known styptics, while acetic acid, an acid which easily dissolves protein, has, for this reason, no similar power. The hydrochloric acid, in very dilute solution, and the acetic acid, easily dissolve fibrine; the former exists in the gastric fluid*, the latter makes meat tender (as it is called) and assists digestion. Stable proteine-compounds, such as fibrine and albumen, kept for some time in extremely diluted hydrochloric acid ($\frac{1}{1000}$), are completely dissolved, without any other substance needing to be added†; a property by which the effect of the free hydrochloric acid of the gastric fluid is illustrated.

Further, many acids may enter into chemical combinations with sulpho-phospho-proteine; for instance, sulphuric acid and hydrochloric acid; and they form under certain circumstances less soluble compounds, for which reason they are powerful remedies in putrid fevers, scurvy, &c. [But acetic and citric acids, which dissolve the proteine compounds, are still more powerful]. These compounds are—

evident, from these facts, that the ashes contain neither an alkaline carbonate, nor carbonate of lime, nor free alkali. The alkaline reaction of the blood, therefore, cannot be due to a free alkali, or an alkali combined with an organic acid; and Enderlin concludes that it must depend on the blood containing tri-basic phosphate of soda ($3 Na O, P_2 O_5$) a salt of which the ashes of blood contain 22 per cent. and of which the composition is not altered by a red heat.—J. P.

* Blondlot (*Traité de la Digestion*) has lately found that the gastric fluid collected pure from the dog's stomach produces no effervescence with carbonate of lime, and that what is evaporated from it in the most careful distillation of very large quantities presents no trace of acid reaction. If this be true, the gastric fluid can contain no free hydrochloric acid.—J. P.

† When hydrochloric acid alone does dissolve coagulated albumen, it does it so slowly and imperfectly, that one may suspect that it has no influence till the spontaneous decomposition of the substance has commenced, and that its action in this case is only the same as that by which it acts on the same substance after the stability of its composition has been shaken by pepsin.—J. P.

The two last (sulpho-bi-proteic, and hydrochloro-bi-proteic acids), are prepared by dissolving coagulated albumen from eggs in acetic acid, and adding sulphuric or hydrochloric acid to the solution, and washing the precipitate with alcohol. Brughauer has found that both of them, if obtained from uncoagulated albumen, will completely lose their acid if kept for six weeks under water.

Lastly, sulpho-phospho-proteine can be combined with some basic salts. The combination which is found in caseine is especially deserving of attention; it contains bone-phosphate of lime ($3 Ph_2 O_5 + 8 Ca O$), a salt which (in any case, a phosphate of lime) probably occurs in fibrine and albumen, and is by these carried to the bones. In casein (and therefore in milk,) it is present in large quantity, and thus a great amount of bone earth is added in a short time to the soft bones of the young animal. Metallic salts and metallic oxides introduced as medicines, or as poisons into the body, may in like manner unite with the proteine compounds and form various proteates (with sulphur and phosphorus), which must of course act peculiarly in the body. Most of these compounds are insoluble, and thus resist the incessant chemical transformation of substances which goes on in the organism; hence arise peculiar conditions of the body, which, carried to a high degree, are destructive of life. It is thus, though not thus alone, that salts of silver, lead, mercury, &c. are poisonous when they are introduced in large quantities into the body.

Proteine is a complex substance, that is, it consists of certain heterogeneous bodies combined in one whole. Different substances, therefore, come forth under the influence of powerful agents.

When proteine is brought into contact with an alkali, ammonia is immediately developed. We can hardly make the alkaline solution weak enough to prevent the development of ammonia. When fibrine, or coagulated albumen, is dissolved in a weak potash-ley, we always see a development of ammonia. This property is, in connection with the alkaline property of the blood, of the highest importance: by it a leading property of proteine in the animal body is explained, namely, that it is in a state of constant change.

If albumen, or any proteine-compound, be boiled with potash, it is wholly decomposed. The products derived from the decomposition are certainly not all constituents of the proteine, but there are undoubtedly some among them which must be considered as constituent parts of it. They are the following:

		C.	H.	N.	O.
2 equiv.	Leucine . .	24	48	4	8
2 "	Protide . .	26	36	4	8
2 "	Erythroprotide	26	32	4	10
4 "	Ammonia .	—	24	8	—
2 "	Carbonic Acid	2	—	—	4
1 "	Formic Acid .	2	2	—	3

2 equiv. Proteine
+ 9 Water = 80 142 20 33

Leucine is a crystalline substance, which is also obtained from gelatine, and which thus marks a connection between the composition of proteine and the substances which yield gelatine. Under widely different circumstances it is obtained, with or without sugar of gelatine, from fibrine, albumen, caseine, and gelatine: *e.g.* from rotting cheese, and by boiling fibrine, albumen, or caseine with potash, we obtain leucine by itself; we obtain sugar of gelatine, by treating gelatine with sulphuric acid; and a mixture of sugar of gelatine and leucine by treating flesh with sulphuric acid or potash, or by treating gelatine with potash. Leucine and sugar of gelatine are, therefore, substances nearly allied to each other; leucine is to be regarded as an integral part of proteine.

The two other bodies, protide and erythroprotide, are extractiform substances (the latter is of a red colour), which are nearly related to gelatine.

Of the other three products of the decomposition of proteine by potash, the carbonic and the formic acids unite with the potash, and the ammonia is set free.

So long as it is unproved whether leucine occurs in the animal body, or that it is consumed in some of the secretions, this decomposition of proteine by alkalis admits of no application in the living organism. The analogy, however, between the two extractiform substances and gelatine deserves especial remark, and teaches us with some probability that, if animal cellular tissue is derived from proteine, this is effected by a similar trans-

formation to that observed under the influence of alkalis.

It still remains for us to consider under what form proteine occurs in the animal body. The proteine of plants being combined with sulphur and phosphorus, or presented with these and phosphate of lime to animals, vegetable food is no more pure protein than animal food is. It is much to be regretted that we are almost wholly ignorant of the quantities of phosphorus and sulphur which occur in the vegetable proteine compounds; and so long as this ignorance lasts, nothing can be said with certainty of the formation of the animal from the vegetable proteine compounds, except that the proteine (pure) of the vegetable food passes unaltered into the animal body. But the formation of the albumen of serum, of fibrine, of caseine, &c. all proteine compounds, which it is probable do not occur in this form in plants, requires a yet further illustration.

In the animal body we are acquainted with proteine-compounds under various forms; in combination with sulphur—with sulphur and phosphorus—with sulphur, phosphorus, and alkalis—with sulphur and phosphate of lime—lastly, with oxygen.

In the state of solution, a compound of sulphur, phosphorus, and proteine occurs in the serum of blood, which has many properties in common with vegetable albumen, and with the albumen of fowls' eggs. It is especially in this form—as albumen—that proteine is found in various parts of the animal body. One examines no organ, no fluid (except those belonging to the secretions) without finding it. If one kneads, for instance, a minutely divided organ, a liver, kidney, or lung, with water, one obtains albumen coagulable by heat. It is found, too, in the lymph, in the effused serum, in the chyle, in pus. But whether in all these sorts of albumen there is always $10(C_{40}H_{62}N_{10}O_{12}) + PhS_2$ is unknown: it is not probable that it is so.

In the brain, the spinal marrow, and the nerves, we find a large quantity of a substance similar to albumen, but firmer; so that, inasmuch as it is not so easily soluble in cold water, it appears to agree more with the solid albumen of the oily seeds. Brains rubbed with water yield just such an

emulsion as oily seeds do. The composition of these cerebral proteine-compounds, however, is as yet unknown; it is as well to stamp them all with the name of albuminous matter till we become better acquainted with them.

In milk, together with fatty matter, a sulphur-proteine compound occurs free from phosphorus. This is caseine, distinguished by its property of being precipitated from its solutions in water by rennet, acids, and especially lactic acid. Caseine [is said] to have been found in many other animal fluids; in saliva, bile, pancreatic fluid, in the crystalline lens, in pus and tuberculous matter, and, which is most important, in blood. But as all these conclusions are drawn from observing the traces of its properties, and not from analyses, the point is not to be considered as proved; though it would not be strange if caseine really occurred in the blood, since it may be readily formed by the removal of the phosphorus from the albumen of the serum, or from the fibrine. And so of other proteine compounds. They, and perhaps the whole series of the albuminous substances of the brain, liver, &c. may be derived from the albumen or fibrine of the blood by a very slight alteration in the proportions of sulphur and phosphorus.

With regard to the fibrine of the blood, the first thing to remark is, that it exists in this form, not in the blood, but out of it. It forms the fibres of the muscles, fibres whose chemical composition is known to be a proteine-compound, but concerning which we are not as yet completely instructed. Their properties, agreeing with those of the fibrine of the blood, afford reason for thinking that they are chemically identical.

The fibrine of the blood, we know, appears in the act of coagulation. After coagulation we find stringy substances in the blood, which before were not found in it. The fibrine is said to be dissolved in the blood. But it is in a high degree improbable that this can be taken in the literal sense: the fibrine appears rather to be in a semifluid state in the blood.

Again, a third proteine-compound occurs in the blood, that, namely, which composes the cell-membrane of the

blood-corpuscles, and which is, on this account, named *globuline*. Simon regards it as caseine. That it is a proteine-compound is beyond contradiction, but what it is, is at present unknown. As little, also, do we know what substance there is in the nucleus of the blood-corpuscles, and what is the fluid which is enclosed with the colouring matter in the membrane.

All these proteine-compounds of the animal body contain phosphate of lime in various quantities, and its quantity is not the same in the corresponding substances taken from different animals.

Two more very important proteine-compounds occur in the animal body, namely, the bi- and tri-oxypoteine (or binoxyde and tritoxye of proteine). Both occur in large quantity in inflammatory blood; they form in respiration, and are a common constituent of the blood; the latter is soluble, the former insoluble, in water; both are products of oxydation in boiling fibrine in water; the latter is formed, also, in the boiling of albumen, and is a product of the decomposition of the chlorite of proteine; the former may be extracted from hair by means of an alkali*.

We find both these compounds, as constituents of the healthy organism, in the blood, in which they are formed in small quantities at every inspiration; and (as we shall presently explain in speaking of the colouring matter of the blood) it is probable that a thin layer of them, composed like an inflammatory buffy coat, is formed on each blood corpuscle [so as to modify the natural dark colour of the corpuscles, and make the mass of them appear scarlet, as venous blood does when seen in a milk-white glass]. They are products of the oxydation of the substance which, in the coagulation of the blood, becomes fibrine, and which in the lungs, receives oxygen, and circulates through the arteries in the form of the two oxydes of protein. In the capillaries they are decomposed and used in nutrition. Too great a quantity of these oxydes produces inflammation.

* A complete account of Mulder's researches on these two proteine compounds is given in the MEDICAL GAZETTE of the 9th of last February, by Dr. Golding Bird; but at p. 615, by an accidental transposition of lines, the binoxyde is said to be soluble and the tritoxye insoluble in water: the truth, as the rest of the paper shows, is the reverse of this.

Tri-oxy-proteine occurs in pus, and is by some called *pyine*: bi-oxy-proteine forms tissues.

We cannot determine with certainty, how, and under what circumstances, proteine is prepared by plants. In examinations of mould-plants of the lowest formation, I have always found proteine in them, and this derived from non-azotized substances dissolved in water, and exposed to pure atmospheric air. Proteine is not absent in the very youngest radicles of plants; it therefore, like dextrine and cellulose, is among the very first of vegetable products. Without it, no organization in the vegetable kingdom appears able to exist Since, then, it is certain that both dextrine, and cellulose, and proteine, are derived straightway from the food of plants, so it is probable that all the proteine which is found in the whole plant is formed at the extremities of the fibres of the root. Thence it may penetrate in the soluble state with dextrine through the cells already formed, to form elsewhere new cells, *i. e.* a combination of cellulose and proteine in, as it appears, definite proportions; or else, having been precipitated here and there in the solid form, they may be made soluble again, and transferred to other parts (see page 824). For many plants, indeed, a small quantity of proteine may suffice, although it is indispensable to the formation of every new series of cells. If one takes into consideration its excess in young cells, and the small quantity of it which there is in old ones, it is probable that the same quantity of proteine is applied to a thousand purposes in one and the same plant, being formed in the radicles, then deposited somewhere else, and afterwards again dissolved and carried to some other part. It may be believed, that it is very seldom consumed in plants; it appears, however, to be used in some families of plants for the formation of vegetable alkalies and other azotized substances, and it certainly forms chlorophyll, indigo, &c.

CASE OF DISEASE OF THE COLON.

To the Editor of the Medical Gazette.

SIR,

As the following case, though perhaps not of a very extraordinary kind, may not be without its use in the diagnosis of somewhat similar forms of disease, I shall be obliged by your giving it a place in your pages.

I am, sir,

Your obedient servant,

F. B. PRING,

Member of the Royal College of Surgeons.
Graddington, Yorkshire,
August 29th, 1844.

Mr. —, twenty-five years of age, complained occasionally of pain in the left side, between the ribs and the spine of the ileum. He frequently passed a great quantity of blood from the rectum: his stomach was in a very irritable state, rejecting nearly all kinds of food, and latterly he vomited frequently a bilious fluid. His pulse varied from 100 to 120. Countenance cadaverous, perhaps in some measure from loss of blood; bowels generally relaxed; tongue not coated, but white. His nights were restless, but he slept frequently during the day. He had been six months under treatment in London by men of eminence before my seeing him. He had been salivated, had taken the compound decoction of sarsaparilla, and an issue had been made in the loins.

On examining the side in the situation of the pain, an enlargement of an oval shape was distinctly felt under the last ribs, pointing towards the groin. The situation of the tumor was such, that it was suspected by a professional gentleman of Leeds, who saw the patient in consultation with me, as well as by myself, to be an enlargement of the spleen, or a tumor immediately contiguous to this viscus. The most distressing symptoms appeared to proceed from the excessive irritability of the stomach. It was therefore agreed to give small doses of laudanum and prussic acid; to relieve the bowels by injections occasionally, if required, and apply blisters over the stomach. The skin covering the tumor in the side was also blistered, and the iodide ointment was rubbed in. Under this treatment our patient felt considerably relieved from the pain in the side, and other

symptoms ; but there was no essential amendment, as in about six weeks he died.

On examination, twenty-four hours after death, the stomach was found to be in a healthy state; the liver of a pale ash colour, and the gall bladder distended with bile, some of which had exuded through its coats, tinging the parts adjacent. The pancreas was healthy, and the spleen small, but not diseased. The kidneys natural, and the ureters and bladder filled with urine. On tracing the intestines from the stomach, they were found healthy until arriving at the descending portion of the colon, where there were extensive adhesions. This portion of the bowel was much thickened, forming a tumor of a scirrhus kind, and an ulcerous opening was discovered in it, from which the contents of the intestine were prevented escaping only by its adhesion to the parietes of the abdomen. The rectum was partly filled with feces.

ON THE
PATHOLOGY AND TREATMENT OF
OVARIAN DISEASES;
WITH CASES.

By DR. SAMUEL J. JEAFFRESON,
Physician to the Chelsea, Brompton, and Belgrave
Dispensary, &c.

[Continued from p. 801.]

General plans of palliative treatment may be considered as they refer to the general health and constitutional powers of the patient, to functional or organic derangements of distant parts set up by sympathy or other causes, or to the ovarian tumor itself.

Whilst I would strongly urge upon practitioners the vast importance of this subject, both as respects the comfort and even the life of the patient, (for difference in management may make many years difference in life), I shall not venture to do more than give a very brief sketch of a subject, the more detailed and minute consideration of which might prove tedious.

In the more advanced stages of ovarian disease, the constitutional powers are for the most part broken down more or less, and require therefore such means, both medicinal and dietetic, as are best calculated to support the

strength of the patient. Such is, however, by no means universally the case in the earlier stages of the disease, in which the existence of a plethoric habit, with general heat of skin, quickened circulation, and inflammatory tendencies, may require the use of cooling and evacuant remedies, spare diet, abstinence from stimulants, &c. Often, on the other hand, up to a very late period in the disease, no peculiar condition of the general health exists to demand especial interference or attention. Peculiar diatheses may require especial attention, throw much light on the pathology of the affection, and lead to the employment of means powerful in arresting, nay, sometimes perhaps even in curing, the local disease. I would be understood to allude more especially to the strumous diathesis, in which case certain remedies useful in many other affections of strumous origin afford increased hopes of advantage as respects their effect, through the system at large, upon the local disease. Such remedies are mercurial alteratives, tonics, liquor potassæ, iodine and its salts, as the iodide of potassium, some of the preparations of iron, &c. These remedies will, however, be more fully considered hereafter.

So many and varied are the functional and organic derangements of distant parts which may be set up in the course of ovarian disease, either by sympathy, mechanical inconvenience, or other causes, that it would be almost impossible to enter into all these circumstances. In the earlier stages, the pelvic viscera may be affected by inflammation, or the natural outlets of the bowels and bladder may be obstructed by compression: purgatives and enemata would appear to offer an easy remedy for the former, the use of the catheter for the latter inconvenience: these difficulties are not, however, always so readily overcome; and more than one case is on record, in which puncture of the bladder above the pubis has constituted the formidable alternative for relieving the distension of this viscus. Some mechanical advantage may perhaps occasionally be obtained by tilting up the tumor with the finger introduced either into the vagina or rectum. Leeches, cupping, &c. afford relief by temporarily diminishing the vascularity and bulk of the tumor.

As the disease advances, inflammation of the peritoneum, general or partial, or of the various abdominal viscera, may demand our care. These must of course be treated according to their urgency and importance, bearing in mind the persisting nature of their exciting cause, and the state of the general vital powers. Whilst, therefore, general principles of treatment are adhered to, some cautions will be required not to carry general blood-letting, and the use of mercury, &c. beyond such a point as will be safely borne by the patient.

An irritable state of stomach, and constant vomiting, may require all our skill and tact to surmount. Here we should be careful thoroughly to unload the lower bowels, and if the irritability of stomach still continues, the effervescing salines, with small doses of some opiate, hydrocyanic acid or kreosote, sinapisms, and small blisters to the epigastrium, may be used with advantage. Obstinate constipation, or equally obstinate relaxation of the bowels, may accompany the disease in its further progress. Excessive flatulence is very commonly observed, and greatly aggravates the sufferings of the patient by augmenting the distension of the abdomen. The abstinence from all articles of diet most liable to induce flatulence, and the use of carminative medicines by mouth, or carminative injections, are measures, therefore, the judicious adaptation of which will often be attended by great relief. Amongst the carminative injections I have found that of the Confection of Rue, ʒj. vel ʒij. to the pint, as recommended by Dr. Seymour, one of the most efficient.

Ascites may complicate the ovarian disease, and still more infringe upon the distensive powers of the abdominal walls. The means of most avail in ordinary ascites will but too frequently fail us here, or at least afford only temporary relief; the ovarian tumor, the exciting cause of the ascites, being still in existence.

Lastly, urgent orthopnoea and dyspnoea augment the sufferings of the patient, and threaten death by suffocation; these symptoms, due to the enormous distension of the abdomen, and consequent pressure on the thoracic viscera, can rarely experience more than temporary relief and abatement from all our skill. The two last subjects,

therefore, naturally lead to the consideration of

The palliative treatment of ovarian disease by surgical means, or paracentesis.—A great dread of this operation appears to have been entertained by the older practitioners; and even in the present day, if it be regarded with less timidity, the operation cannot be said to be one which is generally looked upon with much favour, its performance being considered in most instances as the last, and that but a temporary palliation of the disease. Authors have not, however, been sufficiently explicit in stating the grounds of their positive dread, or more tacit distrust of the operation; and, so far at least as my own experience goes, I think it would be difficult, from published records of ovarian disease, in which it has been performed, to draw up any very satisfactory statistical table, illustrative of its results.

Independently of ascites in this instance, a secondary affection, paracentesis, is of course applicable alone to the entirely fluid form of ovarian tumor, unilocular or multilocular; or to the fluid cysts of the mixed variety. The motives with which the operation is performed are the same in both instances, whilst the results obtained and the risks incurred are very different.

To paracentesis, in the unilocular variety of the disease, it may be objected chiefly that the rapidity with which the cyst refills is apt to accelerate the fatal termination of the case, by the consequent increased drain upon the system thus induced. Against this view of the subject, however, must be set the fact, that it snatches the patient from the immediate risk of death by suffocation, exhaustion, &c.; that it frequently affords immense relief to the sufferings, and that great numbers of patients have survived very many years, under the occasional repetition of the operation, to enjoy a very fair share of health and happiness during the intervals. In illustration of this fact, I may refer to Case No. III. Numerous other, and more striking instances, might, if necessary, be adduced. The re-accumulation may be very rapid, or it may not; we have no certain means of foretelling this. One source of failure may sometimes exist in the delay of this operation till the powers of the constitution are already too broken and

dilapidated. Paracentesis has occasionally, though very rarely, been followed by permanent cure. A curious case is related by Dr. Ogden, of Rochdale, in the 26th Vol. of the *MEDICAL GAZETTE*, in which the patient, a Mrs. Jackson, æt. 32, had been previously healthy till the birth of her last child. Five months previously to her present attack the catamenia ceased; to this succeeded sickness of stomach, abdominal swelling, &c. and ultimately entire retention of urine. In this state Dr. Ogden found her, the patient considering herself pregnant. The retention of urine persisted; from the tortuous and compressed state of the urethra, it was found impossible to introduce a catheter. On examination per vaginam a tumor was discovered occupying the whole of the sacrum, and allowing little more than a finger to pass between it and the pelvis. A segment of the os uteri could with difficulty be felt above the pubes, which led in the first instance to the supposition of a retroversion of the uterus. On the left side of the vagina was found an elastic tumor, supposed to be the fundus of the bladder. In consultation and conjunction with Mr. Beckley, the bladder was punctured above the pubes, and two pints of high-coloured urine were abstracted. Being again, however, foiled in their careful attempts to pass the catheter, it was now resolved to puncture the tumor in the vagina, under the conviction that it was a fluid ovarian cyst. This operation was accordingly performed by means of a trochar. Four quarts of semi-transparent fluid were drawn off, which gave the patient great relief, and restored the action of the bladder; she was able to void her urine naturally an hour after the operation. The discharge from the ovarian sac continued for several days, and a permanent cure ensued.

I am inclined to suspect of this, as of the case before quoted as occurring to Dr. Mead and Dr. Ramsbotham's father, that the tumor was originally of the mixed kind, and had undergone the spontaneous process of softening. The tumor would probably, if left to nature, and had the patient survived, have ruptured itself in this situation; a process which was in this instance at least happily anticipated by the skill and boldness of her medical attendants.

It is remarkable, that whilst this case terminated in a permanent cure, in the two others the rupture of the sac was only followed by temporary relief. In the case related by myself, No. V. the rupture of the sac occurred in the recto-vaginal septum. An equally interesting and somewhat similar instance is recorded by Dr. Seymour, in his *Gulstonian Lectures*, as having occurred to himself. The patient had previously been under the care of his colleague, Dr. Badeley, for a very large ovarian tumor, which was hard to the touch, and irregular in its surface; the rupture of the sac was preceded, as in my case, by manifest softening of the tumor, and occurred also into the recto-vaginal septum. A case is also quoted by him, as having occurred in the practice of the late Dr. Warren, in which permanent cure followed a rupture of the sac into the large intestine. In this case also the rupture was preceded by manifest softening of the tumor, although we are not informed of the reasons which induced Dr. Warren to assume that the rupture took place into the great intestine, or what was its exact site. In the cases formerly quoted, as occurring to Dr. Blundell and Mr. Abernethy, I have already stated my reasons for believing with Dr. Ramsbotham that the cure was owing to a rupture of the sac into the bladder; another interesting case is related by Mr. Maclure, in a paper read before the Harveian Society, in which the tumor ruptured into the bladder. All these cases terminated in permanent cure. Now it is remarkable that whilst so many cases of permanent cure are observed when the rupture of the cyst has occurred in these situations, none hardly are to be found on record (at least, so far as my own limited means of research allow) where natural or artificial outlets have been established in the neighbourhood of the umbilicus. Many authors certainly speak in general terms of cures thus effected; but the general assertion is unfortunately not confirmed by the positive evidence of cures; more or less temporary relief being the only advantage obtained in the majority of cases related.

It is impossible not to connect the results observed with the situation of rupture; and it would appear probable that where this takes place at the most

dependent part of the cyst, its contents are thus more thoroughly and effectually emptied; and the sac perhaps completely collapses, and undergoes such changes, whether inflammatory with adhesions, or positive waste and atrophy, as to preclude the recurrence of subsequent secretion of its contents, and consequent distension. This is rendered the more probable, in that, in all the cases recorded of permanent cure, the first rupture of the cyst has been succeeded either by some continued drain for some days or hours, or by the re-rupture of the cyst after a day or two, as happened in my own case.

Could this view of the subject be rendered available in practice? Would it be practicable to imitate the process of nature? and might not the operation performed by Dr. Ogden, and so successful in its issue, be applicable in some other instances? It will be sufficient here to have thrown out the suggestion; such a plan could only of course be adopted in a few instances, and its applicability is rather a subject of consideration for the surgeon than the physician. I shall have occasion again briefly to revert to the subject, when speaking of the surgical means employed for the permanent cure of this disease.

It will not be necessary to say more than a few words on the subject of paracentesis in the multilocular and mixed varieties of tumor. It is in these cases that the most immediate risk to life attends the operation. Re-opening of the puncture is apt to occur, most likely from the degree of tension exercised on the abdominal parietes by the remaining portions of the tumor, whether solid or fluid; for wherever the fluid contents are separated into various compartments, if these be entirely separated from each other, the one punctured will alone be emptied by the operation. Peritonitis is also too apt to follow the use of the trochar in these cases, and that too of a low and most fatal character. This is probably due to the circumstance that the punctured cyst, retained in a certain position by its connection with the other portions of the tumor, collapses in such a manner after withdrawing the trochar as to allow of the escape of some portion of the fluid contents of the cyst into the peritoneal cavity.

Under these circumstances it need

hardly be said that the operation is as much as possible to be avoided, and it even becomes a question whether we ought at the urgent desire of the patient to afford her temporary relief by means of an operation, by no means very painful, but which risks the abrupt fatal termination of a case, which, left to nature, aided by art, might by a bare possibility end in the universal softening of the tumor, spontaneous rupture, and cure.

Acupuncture has been recommended by some practitioners in the case of fluid ovarian tumor; but I am not aware of many instances in which the result of this practice has been publicly recorded. One interesting case, however, has been published in the *Lancet*, by Dr. Robert D. Thompson, in which he had recourse to this mode of treatment. Acupuncture was first practised in May 1838; the patient bore the operation well, and became much smaller in bulk: in March 1839, she was perfectly free from any disease.

In ascites complicating ovarian disease, paracentesis can hardly be recommended; it may be performed at the request of the patient as a means of temporary relief, but it is not likely to effect a permanent cure of the ascites, the exciting cause of which is still remaining.

The medical treatment to be adopted for the permanent cure of ovarian disease comes now to be considered; and happy, indeed, should I be, if I had much that was new and valuable to communicate on this head; it may not, however, have been altogether an unprofitable task to have brought together from my own limited personal experience, and from the records of others, additional evidence in confirmation of former opinions.

When we consider the prodigious amount of fluid depositions which are effused within the serous cavities and loose cellular tissues in some forms of dropsy, or of synovial fluid in rheumatism, or other diseases affecting the large joints, sheaths of tendons, &c., and that all these deposits are, under favourable circumstances, removed by nature under the assistance of our art, it appears strange that ovarian cysts, multilocular or unilocular, should be so perfectly organized as to be capable of secreting such enormous collections of fluid, and yet apparently be possessed of little or no power in effecting

their reabsorption. That this, however, is the case, is a matter of but too general experience; hence hydragogue purgatives, diuretics, and other remedies powerful in promoting the removal of other dropsical effusions, are of little or no avail in this disease. Indeed, it not unfrequently happens, that the employment of the more powerful remedies serviceable in general dropsy, in these cases, either from a mistaken diagnosis, or an erroneous impression of their applicability, is attended with considerable mischief to the patient's general health, and consequently even to the ovarian disease, whose removal they were intended to effect. Should the slightest doubt exist in the mind of the practitioner as to the real nature of the affection, it is of course right to avail himself of those remedies which are useful in ascites, some of which may, indeed, prove useful as palliatives in this form of disease; but the utmost caution should be observed to avoid the infliction of constitutional mischief.

Many remedies, indeed, are enumerated as useful in the treatment of ovarian disease, but authors have not always been sufficiently explicit in describing the particular form of the affection to which they are applicable. It is, I suspect, in the mixed form of tumor that these remedies, of which I shall presently have to speak, have been found beneficial.

No remedy with which I at least am acquainted can be with any certainty depended upon, as curative of the fluid varieties of ovarian disease. Emetics, indeed, have been highly extolled by the older practitioners; and from the known effects of these agents in promoting absorption, there would appear at least to be some grounds for their trial. Emetics appear to be much less frequently employed, under all circumstances, by modern practitioners, than they formerly were. It is true that more extended therapeutic resources may in many cases have banished their use for that of remedies less annoying and equally efficacious; but there seems some reason to believe, that if our forefathers erred in their abuse, we err sometimes no less in their neglect. I must, however, confess my own inexperience of this mode of treatment in ovarian disease.

Whilst, however, we have little hope of inducing a permanent cure of this

form of ovarian disease by the use of general means of treatment, it must not be forgotten that in some few instances a cure has followed the employment of the palliative treatment; whilst in others the further progress of the disease appears to have been entirely arrested, or so greatly retarded, as to enable the patient to live many years, if not in perfect, at least in comparative comfort.

General plan of curative treatment, applicable to the mixed form of ovarian tumors.

Looking at the numerous forms and extent of solid as well as fluid depositions the removal of which is within the power of nature, we might be fairly induced to hope that the absorption of the solid portion of an ovarian tumor was not beyond the pale of possibility. Such hopes have not as yet, however, been satisfactorily realized. More, perhaps, might have been even now effected, had the attention of the medical attendant been earlier called to these cases; for it must be allowed that the very advanced stage of the disease, at which we are but too frequently called upon for assistance, must tend in no small degree to cripple our powers of relief. The general slow progress of the disease, too, which almost necessarily implies a no less slow process of cure, may but too often have induced some laxity on the part of the patient as well as the professional adviser in carrying out those means which would appear to offer the best hopes of success. In ovarian disease it frequently happens that the inconvenience experienced up to a certain period is comparatively small; and the patient who would willingly submit to a long and regulated course of medicine and general discipline for other affections, is slow to call for, or, when called, to follow out, the advice of a medical man. There appears no insurmountable reason why the day should not arrive when remedies may be applied with the same degree of success in ovarian tumors as they now are in many cases of bronchocele, enlarged liver, spleen, and absorbent glands; in thickening and consolidation of parts from inflammation, periosteal nodes, &c. &c.

Amongst the remedies which seem most entitled to our confidence as tending to the permanent cure of this

kind of disease, are iodine, the iodide of potassium, bromide of potassium, and liquor potassæ. The effect of these remedies appears to consist in their inducing that softening process in the solid part of the tumors before described, to which succeeds their spontaneous rupture and permanent cure. It must not, however, be supposed that such cases can be accomplished with any thing like the degree of certainty which obtains in the use of some other remedies in other forms of disease. The evidence, however, of the beneficial influence of these agents, is very considerable, and may lead us fairly to expect still more from their earlier application, and more steady, but careful, employment. To go no further than the cases of recovery recorded by Drs. Seymour and Warren, in the very interesting case related by Mr. Maclure, and that by myself, No. V., one or other of these remedies was largely employed; and I have also had several opportunities of witnessing the gradual softening of ovarian tumors under their use, when I have not been able to learn the ultimate termination of the case. This softening process in the tumor, then, appears to be the effect of these remedies; they do not, however, seem to possess much, if any, influence in promoting its direct absorption. What is their precise *modus operandi* it is not easy to decide. Dr. Seymour states it to be his opinion that they induce inflammation of the tumor. That inflammation of an ovarian tumor, set up by whatever cause, may induce softening and suppuration, there can, I think, be no reasonable doubt; but it is questionable whether the curative effects of these remedies are to be attributed to this cause. In Cases IV. and V. there appeared sufficient evidence of inflammation of the tumor even before these remedies were prescribed: in those related by Drs. Seymour and Warren, on the other hand, softening of the tumor is distinctly mentioned as occurring some time after the commencement of the remedies, whilst there is no mention of inflammation, excepting such as appears to have been immediately connected with the adhesion and ultimate rupture (by ulceration) of the cyst; such also would seem to have been the case in the instance related by Mr. Maclure.

Some caution is required in the use

of the remedies here described, for although their curative effects appear similar, yet their action upon the system differs materially. I must confess my own partiality for iodine, which if it be the most potent remedy, is also the one which is attended by the greater risk of constitutional disturbance; it may be used either in tincture, beginning with six or eight drops of the T. Iodinii of the Dublin Pharmacopœia, two or three times a day, gradually increased up to fifteen, or the iodine itself may be suspended in water, or some other fluid, in doses of from a quarter to one grain, or a grain and a half, which may be combined with the iodide of potassium and liq. potassæ. The increased experience now possessed of the internal use of iodine renders its application more safe and practicable; but it should not be prescribed unless its effects can be watched by a medical man. The compound iodine ointment, or simply the ointment of iodide of potassium, may be rubbed into the abdomen either during or independently of their internal administration. It is advisable after a time to omit the iodine and substitute the liquor potassæ. The conjunction of these remedies with other medicines will often be found advantageous, especially with tonics in a feeble state of system; such combinations, for instance, as the iodide of iron; tincture of iodine, with that of the sesquichloride of iron; and the liquor potassæ with the wine or citrate of iron, or the bitter vegetable infusions. The iodine seems to be best borne when the tumor is in an indolent state, and the patient is free from any symptoms of febrile disturbance; although I have not considered the reverse of these conditions incompatible with its use, when the stomach will tolerate the remedy, and when the symptoms are not sufficiently urgent to require the constant use of other remedies of a palliative character, whose administration precludes the use of iodine. The liquor potassæ, or even iodide of potassium, will often be found useful when iodine is inadmissible.

The muriate of lime, formerly much more commonly in use for all forms of scrofulous disease, especially in the glandular enlargements observed in those affections, has been highly extolled by many authors in the treatment of ovarian disease. Dr. James

Hamilton, of Edinburgh, whose opinions are deserving of the highest respect, has borne very strong testimony in favour of this remedy; which, however, it is right to say, he combined with firm pressure upon the abdomen by means of bandaging and frequent percussion. This percussion was effected by means of an instrument consisting of a straight handle, which may be said to represent the wrist, and five metallic prongs, bent, as the fingers may be, at nearly right angles to the handle, the termination of each prong consisting in a round metallic ball of small size. The abdomen is to be percussed night and morning with this instrument for ten minutes at a time; the percussion should be quick and sharp, and the force regulated by the degree of sensation experienced by the patient.

Dr. Ramsbotham is inclined to attribute the efficacy of this practice, if it be efficacious, to the inducement of inflammation of the lining membrane of the cyst; for myself I am more disposed to attribute any advantage thus derived to the inducement of softening of the solid matter of the tumor; and indeed such seems to have been the effect described by Dr. Hamilton himself; but he still further relates many instances of cure apparently by direct absorption of the contents of the cyst. It is but fair to say, that neither in Edinburgh, nor elsewhere, so far as I can learn, does this practice seem to have satisfied the expectations which the high encomiums of so respectable an authority are calculated to excite. How far this may depend upon deficient zeal and energy in carrying it out, it is difficult to say. Not only in ovarian disease, but in all chronic affections, I feel persuaded that this degree of apathy both on the part of the physician and the patient has condemned many a useful remedy to disuse.

When we learn that Dr. Hamilton himself distrusted the efficacy of this treatment after the successful issue of three cases, and did not recommend it to his pupils till four more successful cases had been added to the number, and when too it is remembered that in most if not all of these seven cases the real nature of the disease, as well as the efficacy of the cure, was identified by numerous other experienced practitioners, it is impossible to refuse our

assent to the beneficial effects in his hands of a plan of treatment, equally available to ourselves, if we choose to carry it out with care and patience.

Knowing the effects of pressure under somewhat similar circumstances, we might fairly be led to expect some advantages from its application in ovarian disease, and such indeed seems to be the case. Dr. Hamilton, it was observed, combined its use with the system of percussion, and the administration of the muriate of lime. In Case III. I was disposed to attribute the very slow reaccumulation of the fluid in some degree to the long-continued use of the iodide of potassium, and firm pressure, which, by means of a belt, I kept upon the abdomen for many months after the first operation of paracentesis.

Electricity has had its advocates in the treatment of these affections; I cannot speak of its effects from personal experience, but there seems no reason to doubt that it may occasionally prove serviceable both by favouring the process of softening of solid tumors, and as a direct promoter of the powers of absorption.

Friction steadily persevered in has been also strongly recommended in ovarian disease. There can, I think, be little doubt that this remedy, simple as it may appear, and easy as it is of application, has been but too much disregarded, not only in the treatment of this, but many other affections. The fault rests partly perhaps with the profession, partly with the public, who, like Naaman of old, who refused to wash and be clean, are too apt to require that some great thing should be done. Friction, as applicable to some other affections, appears to owe its efficacy to the promotion of absorption, and it is not unlikely also to assist in effecting the softening process before described. To render its use efficient it should be employed with some tact, and carefully and steadily persevered in for a great length of time.

Mercury.—So powerful an agent in accelerating the removal of some morbid depositions, both solid and fluid, does not appear to have received much sanction in the treatment of these affections. I have not much evidence to offer in its favour, having rarely had recourse to it excepting under the circumstances of unequivocal inflamma-

tion of the tumor or its cyst. Perhaps some part of the abuse which has been heaped upon it may be due to its indiscriminate application, and the carelessness with which it has been used. Some constitutions certainly appear remarkably intolerant of mercury, and especially, perhaps, the strumous: it is not, however, improbable, that in some instances its very careful administration in minute doses may promote the processes of softening as well as of absorption of ovarian tumors.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

"L'auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Hints to Mothers for the Management of Health during the Period of Pregnancy and in the Lying-in Room; with an Exposure of Popular Errors in connection with these subjects, &c.
By THOMAS BULL, M.D. 4th edit. revised. London: Longman and Co.

REGULARLY educated medical men have, as a general rule, set their faces against popular treatises on medicine. For our own part, though we have not acceded in all cases to the adage, that "a little knowledge is a dangerous thing," we are ready to subscribe to it in connection with medicine, in the strict sense of the word; that is to say, in connection with special disease, and the means of dealing with it. There can be little doubt that the class of books, at the head of which Buchan's Domestic Medicine may be placed, far from benefiting mankind, have rather done them a signal disservice. Such works lift the veil of the statue too high, and unaccustomed eyes, dazzled by the spectacle that is revealed to them, are altogether incapable of reading the indications in the countenance of the goddess. These books do in fact deal with what, in reference to the vulgar, may be termed the mysteries of medicine,—the matters which the cultivated understanding follows and appreciates, but which the untutored intellect can by no possibility comprehend. Books that profess to teach mankind at large the art and mystery of medicine and surgery, then, are only sources of mischief, and ought to be discouraged by every proper means.

There is another class of works,
878.—xxxiv.

however, at the head of which, as the oldest, and, as still curious and interesting, may be placed the "Schola Salernitana," which pretend to instruct the community at large on the means of preserving their health and attaining to a green and vigorous old age, which we are inclined to regard as useful, in the same measure as we believe books of the former class to be pernicious. At the head of these books on general hygiene and regimen, as said, stands the "Schola Salernitana"; as perfect developments of the idea there shadowed forth may be mentioned Dr. Combe's works—Physiology applied to the Preservation of Health, and On the Management of Infancy, and the work whose title stands above—Dr. Bull's "Hints to Mothers." Who, possessed of the elements of liberal knowledge, that has read Dr. Combe's elegant volumes, has not read them with equal pleasure and profit? Who has not admired in them the sound physiologist, the excellent practitioner—his twin brother, by the way—the reasonable man, and the fluent and agreeable writer?—But our business is not with our dear friend Dr. Combe, but with Dr. Bull, whom we have not the pleasure to call friend, but whom we should be well pleased to address by the name. What Dr. Combe has done so ably for hygiene and regimen generally, and with special reference to the tender period of infancy, Dr. Bull has done with special reference to the no less interesting and, as society is now constituted, frequently precarious state of Pregnancy, or rather, and to convey an idea of the whole scope of the work, of Wifehood and of Motherhood,—to coin or adopt a couple of words suited to the occasion.

The newly-married woman, the bride, has been an object of interest and tender consideration with semi-barbarous and civilized men in all ages of the world. One of the first forms of worship paid by man to the Divinity appears to have been under the symbol of the Generator; whence the Lingam worship, still general in India, and which in former ages appears to have been all but universal. The Hebrew women held barrenness as the worst of all infirmities: "Give me children, or I die!" exclaims one of our Scripture heroines; and part of the ceremonial that is still observed among the Jews

on the birth of a man-child—circumcision, and among christian nations at the hymeneal altar—the giving a ring—have unquestionable reference to the antique and extraordinary respect in which the generative faculty was held by primitive man emerging into the light of poetry and reflection from the long night of a merely sensual existence.

Even in the polite nations of what we are pleased to style antiquity, Greece and Rome, the women must have been vastly forward in a kind of knowledge in which our females are generally mere infants. Fancy the virgins of Athens decorating an enormous Phallus with wreaths of flowers, and following the article through the streets of their city in solemn procession, singing hymns in praise of Bacchus and the Phœnician Astarte under her Greek name of Aphrodite! We should certainly open our eyes in these degenerate days, did we come upon a train of the virgins of the metropolis engaged in any such proceeding. The women of antiquity could have been in no want of information in regard to the altered circumstances attending their newly assumed state of wife and prospective mother; their minds were prepared for this by all their previous habits, and doubtless also by their elementary education. Ours, once they have entered the cohort of matrons, are unquestionably often exceedingly at a loss; many of them certainly are not yet disabused of the nursery faith in the advent of each new baby from the parsley bed, or of its arrival by the mail-coach with the nurse in the night.

"In the minds of married women," says Dr. Bull, "and especially in young females, those feelings of delicacy naturally and commendably exist which prevent a full disclosure of their circumstances, when they find it necessary to consult their medical advisers. To meet this difficulty, as well as to counteract the ill-advised suggestions of ignorant persons during the period [of pregnancy and] of confinement—are the chief objects of the following pages.

"While it is believed that much of the information contained in this volume is highly important to the comfort and even to the well-doing of the married female, much of it is, at the same time, of a character upon which

she cannot easily obtain satisfaction. She will find no difficulty in *reading* information, for which she would find it insuperably difficult to *ask*.

"There are many little circumstances, too, in which it does not occur to her to seek for advice, of the nature and result of which she ought not to be ignorant. Young married women are especially liable to many needless, yet harassing fears, which it has been the anxious object of the author to remove, by showing that they have no foundation in truth."

In conformity with the purpose thus expressed, Dr. Bull's book is divided into ten chapters, of which eight refer to the mother, and two to the new-born infant.

In the 1st chapter he treats of the management of the health during pregnancy, and of popular errors on this subject—and truly, in excellent taste, under the guidance of good sound common sense; so that not only young married women, but junior members of the profession, may profit by his strictures. He concludes this chapter by some observations on the serious effects which matrimony sometimes, we should say, not *frequently* as Dr. Bull does, sometimes exerts upon young women of delicate health. Certainly nature's institute in reference to the higher forms of animal creation, is not that the parent in giving birth to a new being shall herself cease to be. So untoward an event does occasionally happen indeed, but it is the rare exception to the general rule. Dr. Bull, however, says enough in this place to frighten all delicate young ladies from marrying. Marrying in such cases now and then seems to produce a beneficial influence, but in the majority of instances the result, he says, is far otherwise (p. 7). He very prudently recommends that parents should do all they can to dissuade their children of delicate or consumptive habit from contracting marriage. We entirely agree with our author in the soundness of this advice. We can well believe, however, that he has the same misgivings as ourself of the probability of its ever being followed. Marriage is the crown of female existence, and the female organism that does not crave it, is hardly constituted, nay, is *not* constituted after the most perfect proportions. In spite of the mishaps too through the dis-

agreement of matrimony with particular constitutions, and the much exaggerated perils of child-bearing, it still remains true that married women in the mass have better and longer lives than unmarried women.

The 2d Chapter is entitled, "Of the Mode in which Pregnancy may be determined." We apprehend that there can be no difference upon this point; there is but one mode in which pregnancy can be determined. But this is not our author's precise meaning: it is "of the signs by which pregnancy may be known to have taken place," a chapter in which we find everything that seems desirable, put in the most delicate terms:—there is no indelicacy in any of nature's mysteries when they are treated of by the philosopher and the man of refined feeling. "The first symptom of pregnancy is the omission of that regular monthly return which, in female phraseology, is described as 'being unwell.'" To the general rule of suppressio mensium as indicating pregnancy there are four exceptions: 1st, a young female shall never have menstruated, and yet conceive; 2d, a mother shall conceive while she is nursing and not menstruating; 3d, a female shall conceive, and yet be unwell during the first three, four, or more months of pregnancy; 4th, conception occasionally takes place late in life, after menstruation has apparently ceased for ever (p. 48, 49).

Recent physiological researches enable us to interpret several of those exceptions satisfactorily; in regard to others, they leave us very much in the dark.

Chapter III. treats of the diseases of pregnancy; such as nausea and vomiting, heartburn, costiveness and the opposite, fainting, hæmorrhoids, &c. &c. Chapter IV. is on miscarriage, and the means proper to prevent it when threatened. Chapter V. on reckoning, or the mode of telling when labour may be expected. Chapter VI. contains hints for the lying-in room: Sect. 1, with reference to the mother; Sect. 2, with reference to the infant. Chapter VII. is on the breast—sore nipples, milk abscess, &c. Chapter VIII. treats of nursing, and also of weaning. Chapter IX. is on the management of health during infancy. And Chapter X. on the important subject of vaccination.

Our readers, from this brief sum-

mary, will be enabled to see how much information of a very useful and even indispensable kind is contained in Dr. Bull's unpretending volume. It is a work which the practitioner might often recommend to his prospective—patient, shall we call her? to the primipara, with the effect of saving himself a world of trouble, and the woman he is about to attend a world of anxiety.

MEDICAL GAZETTE.

Friday, Sept. 27, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE MEDICAL PROFESSION BILL —No. VII.

QUALIFICATIONS OF SURGEONS AND PHYSICIANS.

WE paused last week in our progress through the Bill, clause by clause, to give what we believe to be a possible "theory of the measure," which has proved to be so different from aught that had been anticipated by the reformers in the profession, that though imprecated for years, and confidently expected, it fell at last like a very thunderbolt amongst them. Medical reform, with the great body of the agitators, meant participation in the government of the College or Company with which they are severally associated. By the Bill, and the Charter or Charters that must be held to constitute necessary appendices to it, they see themselves letted of everything like a chance either to meddle or make with the concerns of their College or Company—unless, indeed, they choose to go to school again, and present themselves anew for examination; which somehow or other few or none seem disposed to do.

Clause the 14th of our Bill, as we have seen, enacts that the Licentiate in medicine and surgery shall be 21 years of age before he can be regis-

tered. The advantages of this Clause are not so conspicuous on this side the Tweed as perhaps they ought to be held, or as they will appear north of that boundary. We have been accustomed in London to have no young man received either as member of the College of Surgeons, or Licentiate of the Apothecaries' Society, until he had attained the age of 21. We are not informed in regard to the present regulations of the Edinburgh College of Surgeons; but we remember them 25 years ago or so, to have been such that youths of 18 and 19 were currently examined and passed as Surgeons. Here, then, the Bill will do great good. No term of study is prescribed to the Licentiate. He may have studied one year, two years, or three years, as the examining boards, with the sanction of the Council of Health and Education, may see fit to require; but he must be one-and-twenty years of age.

The object, therefore, is obviously to secure a minimum of education and qualification in what we suppose we must call the lowest grade of the profession; in other words, to secure a grade of the medical profession having a minimum of education and acquirement.

We think it right to dwell upon this particular, from having observed that at several of the meetings of medical men which have taken place in various parts of the country, one grand purpose of the Bill has been assumed to be to secure "a *high and uniform* standing of qualification for all members of the medical profession*." The Bill will secure *uniformity* of qualification for the lowest grade only—that of the licentiate; it may be respectable, but it

will not probably be high,—or wherefore the Colleges with their specified long terms of study and more mature age, and their grades of Associates and Fellows?

Whether it be desirable or not to have an inferior grade expressly contrived, will be determined variously by different minds. The framers of the Bill have apparently thought that it would be advantageous. We own that we should be fearful of a class of fags or scrubs in the medical profession, precluded by circumstances from all hope of rising beyond it. The younger members of the profession, both surgeons and physicians, and these often the men of the highest education, have long been found ready to undertake the hardest and most disagreeable offices in the profession. They never felt themselves degraded by them; they had still the beautiful axiom of humanity in their mind's eye—*homo sum, nil humani me alienum puto*; and after a few years they emerged in virtue of the dormant power which lay concealed in the liberal education they had received. The Bill, however, of itself, throws no obstacle in the way of any to rise who has the power. The Licentiate with the minimum qualification may take advantage of the enactments comprised in the 15th Clause, and when he has attained the age of 25 years, having previously prosecuted his studies for five years, he may present himself for examination before one of the Royal Colleges of Surgeons, and being found duly qualified to practise as a SURGEON, he will receive letters testimonial to that effect, in virtue of which he becomes a Fellow of the College where he was examined, and is registered and published to the world with his new dignity.

He who aspires to registration with the rank of physician, Clause the 16th enacts, shall have applied himself to medical studies during at least five

* At the Leeds meeting, for instance, it was resolved "That this Meeting views with satisfaction the approximation made by this Bill towards the attainment of a high and uniform standard of qualification for all members of the Medical Profession, and it is earnestly hoped in the progress of the Bill through the Houses of Parliament, its provisions may be rendered as complete as possible."

years, shall have attained the age of 26 years, and shall be a graduate in medicine of some university of the United Kingdom; but if he shall have attained the age of 40 years, and, after having been examined by the Royal College of Physicians of England, shall have been found duly qualified to practise as a physician, then he shall be admissible to registration as a physician. By the same clause it is expressly provided that no person shall be entitled to be received for examination, for the purpose, of being registered as a physician, on the strength of any foreign degree in medicine, unless it has been obtained after residence within the precincts of the foreign university granting it during at least one year, and after due examination, and upon satisfactory certificates of previous study.—All this strikes us as not only unobjectionable, but as most just and proper. We have heard the difference of age between the surgeon and physician objected to; both might probably have been either 25 or 26,—26, we feel persuaded, is not a day too soon for reception as a physician. It is well also to leave the way open to the attainment of the highest rank. It is not every poor student who knows what a brilliant and prosperous practitioner is shrined in his brain. A door should be left open for such a man; and having reached 40, and worked hard, he may find a welcome, if he chooses, among brethren to whom the accident of early fortune had been more propitious. This is an infinitely more creditable and pleasant way of attaining to the *summos in medicina honores* than that by the purchase of a foreign degree. The agents for Giessen and other German universities' degrees will have to shut up shop forthwith.

Clause 17th enacts—that the same person, if possessed of the necessary testimonials, may be registered as both surgeon and physician; a registered

physician, further, may offer himself for examination before one of the Royal Colleges of Surgeons, and a registered surgeon may present himself before one of the Royal Colleges of Physicians for examination, and being found duly qualified each will be entitled to registration in his new or additional capacity.—This too is reasonable; and we trust that in civil life the double qualification will at once obtain the consideration which it has long held with some of our public boards, particularly the Army Medical Board. The military service of the country was held to require surgeons especially; but the experienced Baronet who has long been at the head of the Army Medical Department, knew that disease in a vast variety of forms did still more mischief than the bullets and sabres of the enemy, and he has therefore for many years held the possession of a degree in medicine in addition to the indispensable diploma in surgery as a great recommendation. All surgeons practise as physicians; physicians in great cities only do not practise as surgeons; we should have been pleased to have seen registration on the double testimonial not merely optional, but in certain cases obligatory.

Clause 18 is an excellent clause, conceived in the best spirit. It enacts, that every person registered after examination as a physician or surgeon under the Act, becomes a Fellow of the Royal College of Surgeons, or Associate of the Royal College of Physicians, from which he receives his letters testimonial; and that should he remove from the part of the United Kingdom in which he obtained these letters testimonial to another part, for the purpose of practising there, that he shall be enabled to enrol himself as a Fellow or Associate, or as both Fellow and Associate, we presume, though it is not so stated, of the Royal College or Colleges of that part of the United Kingdom, without further examination, on

payment of the fees of admission, and on complying with the conditions which are required of other persons who have passed their examinations for the purpose of being admitted associates or fellows of the said Colleges respectively.—This is certainly cement for the disjecta membra of the medical profession. How many young physicians watch the float which they have cast into the well-fished waters of the metropolis for years, without getting more than a nibble now and then, and who yet become thriving doctors in some town of the sister island! It would be hard that such men should feel themselves as aliens in their new place of election. The 18th clause secures them a reception among their fellows there, and makes them at once at home.

MEETINGS OF THE PROFESSION UPON THE SUBJECT OF THE MEDICAL BILL.

SINCE our last we have notice of meetings of medical men, on the all-engrossing subject of "The Bill," at Kidderminster and Hastings on the 16th inst., at Chelsea on the 17th, at Norwich on the 19th, and at Epsom on the 22d.

At the Kidderminster meeting Henry Homfray, Esq. was in the chair, and expressed his readiness to aid in any movement 'that should add to the honour of the medical profession, and promote harmonious feelings among its members.' Mr. Cole, of Bewdley, moved the first resolution, which was seconded by Dr. Roden, and was to the effect,

"That whilst, on the one hand, this meeting hails with satisfaction many parts of Sir James Graham's proposed measure of Medical Reform, it views with the deepest concern, on the other, his statement on introducing the subject of that measure to the House of Commons, 'That quackery could not be put down by legislation,' and is decidedly of opinion that any reform, such as the unconditional repeal of the Apothecaries' Act, would be ruinous to a vast mass of the profession, and fraught with great danger and injury to the public."

The second resolution, in asserting the incompetence or disinclination of the public to discriminate between the regularly educated medical practitioner and the uneducated pretender to medical science, vindicated the title of the former to protection, and pledged the meeting to the opinion that nothing short of summary punishment, by fine or otherwise, would remedy the evils inflicted upon the public and the profession by unlegalized practitioners. In connection with this resolution Mr. Thursfield quoted various instances of malpractice by uneducated men in his neighbourhood, in which death in some of the cases appeared plainly to have been induced by the procedure.

The third resolution, which "disapproved of the constitution of the Council of Health and Education," was moved by Dr. Roden. It was then resolved to frame a petition to the House of Commons on the subject, &c.

At the Hastings and St. Leonard's meeting, which was presided over by Walter Duke, Esq., the first resolution, moved by Dr. Mackness, expressed "disapprobation of the proposed Council of Health and Education, inasmuch as no general practitioner is, by the Bill, proposed to be appointed on it."

The second resolution, proposed by John Savery, Esq., is to the effect, that to repeal the Apothecaries' Act of 1815, without substituting any adequate protection to the great body of medical practitioners, would, if carried, be highly prejudicial to the interests of the profession and to the public welfare.

The third resolution (proposed by Jos. Ranger, Esq.) says: that the Society of Apothecaries are entitled to the best thanks of the profession for having extended the course of study and raised the position of the general practitioner, &c.

Other business, such as framing a petition to the House of Commons, forming a deputation to wait on the member of the Borough, &c. was then got through, and the meeting separated.

A full report of the Chelsea meeting, on the 17th, appeared in the *Times* of Monday last, Mr. Morrah in the Chair. The chairman said that the medical profession had for several years been

very uneasy by reason of the imperfection and injustice of the laws which had in ignorant times been enacted for the regulation of professional matters, and had striven to obtain a large share in the government of their corporate affairs, and a more effectual protection of the public health against the wiles of ignorant and unprincipled pretenders to the art of healing. The government had answered their earnest solicitations by bringing in a bill which entirely contravened the wishes of the entire mass of the profession, which removed every barrier against quackery, and deprived the profession of all semblance of corporate independence. Instead of Sir James Graham's being a bill to regulate, it was literally a bill to annihilate the medical profession.

Mr. D. O. Edwards, in a sensible speech, showed that the grand aim of all legislative enactments was to protect the community—he instanced the mint and the assay stamp of the Goldsmiths' Company. He alluded to the parade of factitious diplomas from the Pharmaceutical Society by chemists and druggists who had no medical knowledge, and avowed his persuasion that perseverance in the course threatened by the Home Secretary would be disastrous to the community. Various resolutions in harmony with the views above set forth were then passed.

The Norwich meeting was held in the Guildhall of the City of Norwich, John Green Crosse, Esq. F.R.S. Senior Surgeon to the Norfolk and Norwich Hospital, in the Chair. Resolutions expressive of obligation to Sir James Graham for the opportunity of considering and discussing the proposed measure; approving of the registration clause, but suggesting that the duty of registering should not be left optional, but be made compulsory; pointing it out as a defect in the bill that it had left undisturbed in their present practice and appointments several persons not now legally qualified; asserting that the Apothecaries' Act of 1815 had been very instrumental in advancing the most numerous portion of the medical profession, and that the Court of Examiners of the Apothecaries' Society were entitled to the thanks of the community; declaring farther that to repeal this act without substituting any general penal clause—by summary

process of easy application—against unqualified persons is a great defect; finally, that the resolutions come to should be communicated to the borough and county members, and a petition to the House of Commons framed in harmony with them. The chairman wound up the business in an excellent oration, in which he particularly dwelt on the necessity of a penal clause to make any legislative enactment of avail.

At the Surrey meeting, held at Epsom on the 22d, Mr. Chaldcott, of Dorking, made some very pertinent observations on the state of the profession previous to the passing of the act of 1815, and as it is now, and as it has become under the influence of that act. The following paragraph conveys a fair idea of the way in which the able mover of the first resolution views the contemplated measure:—

"It is a measure which coolly throws overboard, as it is termed, the respectable, conscientious, and successful execution of a difficult and important trust; unsought by, be it remembered, but enforced upon it, by act of Parliament, and so effectively and ably executed, and carried out, as equally to astonish by its results the public bodies to whose superintendence it was first offered, and by whom it was declined, and the Government who left it in their charge. To repeal, therefore, an act of Parliament which, with all its imperfections, has such acknowledged merits, which affords the only protection, and that very small, at present enjoyed by the legally recognized general practitioner, and by the public, appears to be absurd, as well as mischievous. Gentlemen having obeyed the law, undergone an expensive and laborious education, are to have their only safeguard rudely swept away; and unprincipled, untested men, are to be admitted to free and unimpeded competition with them as candidates for public confidence. The public in general, ignorant of medical affairs, and incapable of a correct judgment as to professional qualification, too readily yields credence and confidence to the ignorant, unscrupulous, and artful pretender."

The Council of the Birmingham Medical and Surgical Association held their first meeting on Tuesday last, in

the Hall of Queen's College, Dr. Neale, Senior Physician of the Town, President, in the Chair, supported by upwards of 100 of the leading members of the profession. The Chairman opened the proceedings by exposing the injurious effects which the proposed enactments of Sir James Graham's Bill would have not only on the profession, but more especially on the community at large.

The Council then proceeded to take into consideration a code of rules and regulations submitted by the Honorary Secretary, William Sands Cox, Esq. having for their object "the protection of the public, the promotion of fair and honourable practice in the profession, and for opposing and discountenancing all practices that may have a tendency to bring the profession into discredit, or lessen its respectability. To arbitrate between its members, and to expel any member who shall be proved to be guilty of irregular and unprofessional conduct;" which were unanimously adopted.

REPORTS,

By H. FEARNSIDE, M.B.,

OF

CASES TREATED IN UNIVERSITY COLLEGE HOSPITAL.

[Continued from p. 847.]

Acute pleuro-pneumonia of the left side of the chest; ægophony; friction sound; pneumonic character of the sputa; epistaxis. Successful treatment by bleeding, cupping, calomel, and antimony, and in a later stage of the case antacids and tonics.

RICHARD UNSDELL, æt. 23, admitted into University College Hospital, under Dr. A. T. Thomson, June 9th, 1843. A man of short stature, rather stout conformation, and sanguine temperament; his occupation is that of a tailor's shopman, and his work is rather light than otherwise; he has always had a sufficiency of food, and has been accustomed to the moderate use of fermented liquors; he is a native of Wiltshire, but has resided in London eight or nine years; his parents are living, and healthy.

He suffered from a mild attack of small-pox twelve years ago, and has also had syphilis, but with these exceptions he does not recollect having had any serious diseases, and his health is generally excellent; during the last few months, however, he has not been so well as usual; he has resided during this

period in a confined situation in the neighbourhood of Oxford Street.

Two days ago, having some business to attend to, he rose early in the morning, and walked five or six miles exposed to a constant drizzling rain; on returning home, feeling much fatigued, he threw himself upon his bed in his wet clothes, and slept for three hours. On awaking he had severe rigors, experienced much pain in the left side of the chest, and difficulty of breathing; finding the recumbent posture to afford him some relief he again laid down for some time, but without undressing. On rising, the pain and dyspnoea returned; he began to cough, and had much thirst, heat of skin, and headache. He went out to the house of a friend, where he had hot flannels applied to his side, and took some hot brandy, rum, and beer. He returned home in the evening;—during the night he was unable to sleep; the pain increased in violence, and was sharp and lancinating, impeding respiration. On the following morning he again had severe rigors; the cough became more violent, and he expectorated some tenacious mucus. A continuance of these symptoms induced him to apply for admission at the hospital in the after part of the day. Upon his reception, 16 ounces of blood were taken from the arm; 5 grains of calomel were given, and ordered to be repeated in the morning; and he was directed to take half a grain of tartarised antimony every four hours.

June 10th.—The surface at present is above the usual temperature, and the skin of the chest is considerably hotter than that of the surrounding parts. The face is flushed, and the countenance restless; he does not complain much of headache, but is unable to sleep. The patient lies with most ease upon his back. His breathing is somewhat hurried—the number of respirations is 26 per minute; he complains of severe stabbing pain about an inch below, and a little posterior to, the left mamilla, felt especially upon attempting to take a deep inspiration. He has a frequent cough, and expectorates much brownish tenacious mucus. The whole circumference of the chest opposite the lower border of the sternum is 32½ inches; and of this the right side measures 16½ inches. Percussion elicits a dull sound over the inferior half of the left side of the chest, both anteriorly and posteriorly. The vocal fremitus over the same extent is abolished. Anteriorly the respiratory murmur is feeble or inaudible over the lower part of the left side, but superiorly it has a somewhat bronchial character; posteriorly the respiratory murmur is inaudible over the lower part of the left side; about the inferior angle of the scapula distinct ægophony is heard, and near the same

situation on the posterior and lateral surface of the chest there is a loud double-friction sound. On the right side the sound on percussion is clear, and the respiratory murmur healthy. Pulse 116, small, but resisting.

The tongue is moist, furred in the centre; he has some soreness of throat, is very thirsty, and has no appetite; the medicine has induced vomiting repeatedly; the bowels are freely open; he has no pain about the abdomen; the liver does not extend beyond two fingers-breadths below the margin of the ribs.

C. C. parti dolenti ad 3xvj.

℞ Antim. Potassio-tart. gr. vj.; Mist. Amygd. Amara, f 3vj.; M. Capiat cochlearia duo sextā quaque horā.

℞ Hydrarg. c. Creta, gr. v.; Pulv. Opii, gr. ss. fiat pulvis, sumendus inter singulas doses mistura.

11th.—He is much freer from pain, and his breathing is less difficult; pulse 96, and softer; the temperature of the surface of the chest is less pungently hot; his bowels are relaxed.

12th.—The mitigation of the symptoms observed yesterday has been transitory; the patient is again worse this morning: this is probably owing to his having imprudently exposed himself to cold in repeatedly getting out of bed, and also to his having had some friends to converse with him yesterday. The pain has become as severe as before, and the cough more violent; he has also much headache,—was unable to sleep during the night, and at one time was slightly delirious. The lower part of the left side of the chest is very tender upon pressure; pulse 108, small, and more resisting; respirations 36 per minute; the expectoration consists of tenacious, slightly reddish mucus; the tongue is more furred; the lips dry and parched, and he is excessively thirsty.

The dulness on percussion over the lower part of the left side of the chest appears more marked than it was two days ago; over the lower part of the right side also the sound is less resonant than natural, and occasionally some sonorous rhonchus is heard.

C. C. parti dolenti ad 3xvj.; Auge Hydrarg. c. Creta ad gr. viij.

13th.—He complains of being exceedingly "nervous" this morning, and is thrown into a state of trepidation by the least noise. The pain in the side is less acute and constant, and the respiration less hurried (28 per minute); pulse 96, and more compressible; the friction-sound is audible over a larger extent than formerly. He has had epistaxis; he complains much of headache, and rambles in his sleep; his bowels are relaxed.

V. S. ad 3xvj.; Adde pulveri Pulv. Ipecac. Co. gr. v.

14th.—The cough is less violent, and the pain less severe; pulse 96, and still somewhat resisting; the thirst and heat of the surface have materially abated. The medicine still continues to induce sickness, but not to the same extent as when first administered; the bowels are freely open; the urine scanty. Œgophony has almost disappeared, and the friction-sound is heard loudly over the middle of the left back.

15th.—He has had epistaxis to a considerable extent during the night; the face is less flushed, and the febrile symptoms generally have materially diminished; he has much less tenderness upon pressure over the affected side; the physical signs remain as before.

16th.—He appears much depressed this morning,—answers questions with hesitation, and has some difficulty in comprehending their meaning; there is a slight appearance of sordes about the teeth; pulse 76, small and compressible; respirations 28 per minute; he coughs less, but the expectoration has the same rusty viscid character as previously.

17th.—The countenance is heavy, and the face more flushed; the intellect appears dull, but there was no delirium during the night; there is more sordes about the teeth; the tongue is dry, and shows a disposition to become brown; pulse 120; respirations 28 per minute. The expectoration has altered in character,—it is now a thin brown fluid, containing shreds and masses of opaque matter. The bowels are rather relaxed; the urine pale and clear.

19th.—There is less heaviness of the countenance and dulness of the intellect; there is also less sordes about the teeth; the tongue is moister, and is rather smooth and red about the tip; the gums are turgid and tender; pulse 104, soft and compressible; respirations 26 per minute; he is completely free from pain about the chest. There is dulness on percussion over the inferior two-thirds of the left side of the chest posteriorly; Œgophony is no longer heard, but the friction-sound is extensively audible; over the lower part of the left side the breath sound is bronchial. The bowels have been much relaxed during the night.

Omittatur Mistura Antim. Tart. Post singulas sedes liquidas capiat. f 3j. Mist. Creta.

℞ Hydrarg. Chloridi, Pulv. Opii, aa. gr. iv.; Mica panis, q. s. ut fiant pil. iv., quarum capiat unam quartā quaque horā. Arrow-root, and two pints of milk, daily.

21st.—The diarrhoea has completely subsided; the countenance has assumed a more

natural expression ; he is able to obtain a considerable amount of sound sleep ; the sordes has disappeared from around the teeth, but the mouth is very sore from the influence of the mercury. He has no pain about the chest, coughs much less, but the expectoration maintains the same characters ; pulse 112, soft and small ; respirations 28 per minute ; the physical signs remain as before.

In the subsequent progress of this case the patient's convalescence was somewhat retarded by a catarrhal attack, but with this exception his improvement was satisfactory. As his appetite became keen he was allowed a liberal supply of animal food, and some fermented liquor ; the only medicine administered was the decoction of senega. Under this treatment he regained strength and flesh ; his cough abated, and the expectoration became trifling in amount. The dulness on percussion upon the lower part of the left side, although diminished both in extent and intensity, did not entirely disappear before the patient left the hospital, and the friction-sound continued audible for a very considerable time. He was discharged from the hospital cured on July 13th.

REMARKS.—There was little difficulty in forming a diagnosis in this case : the sharp lancinating pain of the left side, impeding respiration, and increased by all motion of the chest ; the tenderness of the side on pressure, the cough, and fever ; all rendered the existence of pleurisy of the left side highly probable, and this supposition was confirmed by the existence of a friction sound heard about the inferior angle of the scapula, and ægophony audible somewhat lower in the chest. The abolition of vocal fremitus also, over the lower part of the side, was, as first pointed out by M. Reynaud, another valuable indication of the existence of fluid in the pleura. The situation in which the pain existed was that in which it is most frequently observed in pleurisy ; the inframammary, and inferior lateral regions of the chest, being its common sites.

The next question which presents itself is, was there any other disease than pleurisy ? In simple pleurisy the cough is generally dry, but in this case it was attended with viscid expectoration from within the first twenty-four hours of the attack, and on the patient's admission it had quite the "rusty" character of that of pneumonia. The sound of crepitation was never distinctly and unequivocally heard, but this is easily explicable from the lung being pushed away from the walls of the chest by the liquid effusion. Hence we are fairly entitled to infer the existence of inflammation of the lower part of the left lung, as well as of the left pleura.

As is frequently the case, the *decubitus* in the present instance was upon the back ; the tenderness of the affected side was for some time so considerable, that the patient could not bear the slightest pressure upon it ; he could, however, throughout the attack, lie without inconvenience upon the healthy side ; this was probably due to the effusion never existing in any large quantity, for the doctrine of Le Dran appears to be proved, viz. that inability to lie upon the sound side is owing to the pressure of the superincumbent fluid upon the mediastinum, which yields, and encroaches upon the space occupied by the healthy lung when the patient attempts to make the experiment. It appears reasonable to suppose, however, as was argued by Richerand, and is admitted by Dr. Townsend, that something may be due to obstruction to the dilatation of the side, owing to its being placed undermost.

The *respiration* in the upper and middle portion of the left lung had a bronchial character from the period of the patient's admission ; hence, as there were no signs of condensation of this portion of the pulmonary tissue, its existence must be regarded as a proof of the correctness of the observations of those who assert the presence of bronchial respiration in pleurisy.

The friction-sound in the present instance continued audible for a much longer time than usual ; this was probably owing to the effusion into the pleura never being in large quantity ; the middle portions of the lung were thus never far removed from the parietes of the chest. Dr. Stokes mentions the existence of a friction sound (especially in the weak and feeble) for upwards of four weeks, and Andral has observed its persistence for upwards of three months.

The *ægophony* was remarkably distinct in this patient upon his first admission into the hospital, and continued so for some time. Its existence is not perfectly distinctive of the presence of fluid in the pleura, as it has been noticed in some cases of simple pneumonia ; it has been observed that these were in individuals possessing naturally a high-toned or shrill voice ; hence most of the instances occurred in females. But taken in connection with the other physical signs before mentioned, the friction sound, remarkable dulness on percussion, and absence of vocal fremitus, it is quite conclusive as to the presence of fluid in the pleural sac.

The *epistaxis* observed in this case is not a common occurrence in pneumonia, or pleuro-pneumonia. M. Louis noticed it only in eight cases out of fifty-seven ; in one of these cases it occurred on the first day ; in three on the second, and in the rest from the fourth to the twelfth day ; in three cases it was single, in the rest repeated. In the case upon which these remarks are founded

it first appeared on the sixth day, and it recurred several times.

With reference to the *progress* of the case; after the first bleeding, the operation of the calomel, and the first half-dozen doses of the tartar emetic, the patient was much relieved, and on the second day after his admission there appeared some probability of the complaint being, if not cut short, at least greatly mitigated. Probably from the causes mentioned in the history of the case, the inflammatory action received a fresh impetus at this time, and on the following day the patient was evidently much worse. Free depletion was required to subdue this exacerbation of the disease, and on June 16th there was manifested some disposition to the development of typhoid symptoms. About this time, however, the constitutional influence of the mercury first became apparent, and from this period his improvement was strikingly obvious; he began to have a desire for food; his tongue became moist and cleaner; the teeth lost their sordes; he slept better; and in a few days the cough gradually diminished in violence, and the expectoration in quantity.

The *causes* of the disease in this case are obvious; after fatigue and exposure to the weather, the patient threw himself upon his bed, and slept for several hours in his wet clothes. The effects of this rash proceeding were at once apparent in the pain in the side, the rigors and sensation of general "malaise" which he experienced upon awaking. From the rapid abstraction of heat from the surface of the body, the circulation there was greatly interfered with, and an increased quantity of fluids was directed upon the internal organs, and of these none are more liable to be injuriously affected under such circumstances than the lungs, from the magnitude of their vascular supply. Something might also be due to the local impression upon the parietes of the chest. The certainty of the operation of these causes was increased from the patient's having previously taken active exercise, during which an increased quantity of fluids would be directed upon the surface of the body, and here, as elsewhere, exaltation of function is followed by collapse, in which state it is more than usually liable to impressions from external agencies; again, the exercise had been carried to fatigue, in which state the protecting powers of the system are diminished.

The *prognosis* in this case was favourable as to the immediate result; the patient was young, previously in the enjoyment of tolerably good health, and the disease not very extensive. The right lung was little if at all implicated, and the affection of the left one was limited to the inferior portion. But in cases of pleuro-pneumonia, as has been par-

ticularly pointed out by Dr. Williams, the progress of the disease is peculiarly modified. From the compression which the inflamed lung undergoes by the external liquid effusion, the products of the inflammation are restrained, its whole progress rendered slow, and its effects more permanent. Any false membranes formed upon the pleura have time to become organised, and thus they bind down the lung in a compressed state. The lymph effused in the tissue of the lung may also become the means of the adhesion of the walls of the air-cells and small tubes, and thus more or less of the proper texture of the lung is obliterated. In this condition the lung is subjected to the dilating influence of atmospheric pressure, which of course can only act upon the unobstructed air-tubes, and as a natural consequence these become dilated.

Such a result may be feared with reference to the case before us. Although the liquid effusion never existed in any large quantity, yet it must have been sufficient to exert considerable pressure upon the lower part of the lung.

The *treatment* pursued in this case presented nothing peculiar; from the activity of the disease, and the youth and strength of the patient, free depletion was required to subdue the inflammation. In the present instance both calomel and tartar emetic were administered; in simple pleurisy antimony appears to be less efficacious than in pneumonia and bronchitis, but the coexistence of the former disease in this case rendered its employment desirable. There was considerably less tolerance of the remedy than is usually observed, as it continued to induce sickness for several days. As already mentioned, a striking improvement followed the first indication of the influence of mercury upon the system; so closely indeed, that it appears difficult to consider the connection in any other light than that of cause and effect. The diarrhoea which existed about this time was relieved by the chalk mixture; as a warm tonic the decoction of senega was subsequently given; this remedy appears to exert considerable influence upon some of the excreting organs, and in particular upon the skin and kidneys. The functions of these grand emunctories are thus called into greater activity, and the blood purified from any excrementitious matter which their previous inactivity may have allowed to accumulate.

Under this treatment the improvement of the patient was rapid, and he was able to leave the hospital in little more than a month after his admission.

DR. ARNOLD'S REPLY TO DR.
BINNS' CALUMNIES.

To the Editor of the Medical Gazette.

SIR,

I FEEL assured, in throwing myself upon the respectability of your journal as the medium through which to refute a libellous attack against me, which appeared in the *Lancet* of the 25th April last, and which only reached me here yesterday, you will not fail to publish the following remarks.—I am sir,

Your most obedient servant,

W. ARNOLD, M.D.

Kingston, Jamaica, July 19, 1844.

P.S. The original letters quoted from, I have directed my agents, Messrs. Vacher and Son, of Parliament Street, to show you, or to any other gentleman who may feel an interest in the matter.—W. A.

"A person of the name of Arnold—William Arnold—lately published a work on Fever, in the construction of which he used whole handfals of Lempriere, and complete sheets of Major Tulloch and Doctor Wilson's reports, here and there taking a passage from my tractate of Fever, and, fusing them all into one, dedicated the whole to Sir James M'Grigor! The only original thing about the book is the cool impudence of writing 'Fellow of the Royal College of Physicians' after his name, being no more a member of that learned body than General Tom Thumb the American Dwarf. It is impossible to explain, unless by supposing the man a fool as well as plagiarist, how he could venture to call himself a Fellow of the Royal College of Physicians and in London, when the assumption was sure to be discovered and exposed. I know that Frankland, by virtue of a forged Diploma (according to Wood) became member of the College of Physicians, and that a certain practitioner got knighted by a ruse, though he was never gazetted, but it was left for Arnold boldly to assume the Fellowship without the preliminary step of forgery or cunning."—*Lancet*, May 25th, 1844, page 281.

Thus writes the veritable Doctor Binns, the fire of whose wrath it would appear is never to be extinguished. It is not the first foul calumny he has levelled at me since I quitted London, which I treated with the contempt it deserved, and had it not been for peculiar circumstances, I should not have condescended to reply to the above incomparable specimen of malignant falsehoods.

My work on fever was published in the year 1840, and was well spoken of by the London journalists, whose critical acumen

is at any rate equal to the foul defamer of my name. He accuses me of plagiarism: I most solemnly declare that I never saw Lempriere's work in my life, and I challenge the world to identify a passage I have used either from that, or any other work; and as to his contemptible tractate, as he calls it, the whole of my work was written long, very long, before I had the immeasurable misfortune of becoming acquainted with so reckless a libeller; the matter that is inserted in my work as an appendix was obtained under the sanction of my friend Sir James M'Grigor, who at any rate knows that I am no impostor, and knows well, right well, that all my titles have been honourably obtained, as the records of the Colleges I belong to will prove.

Mark how consistent this defamer, this Binns, proves himself to be, in the remaining part of his paragraph; and what must the world think of that man who could pen such trash and falsehood, knowing, as he must know well, that he is the writer of the following letter, and review of the very work he now so unsparingly, so incautiously, so vainly, and so impotently, attempts to condemn?

December 7, 1840.

"Dear Arnold,—I wrote you on Thursday evening, and inclosed a letter from Harding, I waited this evening, it being your lecture night; you would have awakened the echoes of my modest domicile. I inclose you now a leaf of the Woolwich paper with the *critique* on your yellow Jack book; there are one or two rather queer blunders in it, poor Grant not being a scholar, but on the whole he has executed the task not so worse."

Here is the Doctor's notice of my yellow Jack book, as he terms it.

"Fever has occupied the attention and excited the labours of all medical men, from the very infancy of the curative art, to its present, we would fain say, healthy adolescence—yet strange to add, so Protean have been the forms, types, or symptoms of the disease, or so dissimilar their effects upon different constitutions, that scarcely any two writers have agreed either on the name, the treatment, or the proximate cause of the malady. While one has attributed the morbid action to the nerves, another has as positively asserted that it commences in the solids; a third alleges he has found the semina of fever in the brain; and a fourth, disagreeing with the theories of the preceding, and finding the language of the lecture-room exhausted, boldly strikes out a new path, and discovering a terminology for himself, surprises and perplexes us by gravely affirming that fever is the consequence of an *error loci*! But what this new principle is, whether malaria, fomites,

solar or lunar influence, night dews or animalcula, the theorist is by no means prepared to prove. In the work before us these glaring errors of an ambitious philosophy have been carefully avoided, and the author presents us in a plain, but by no means rustic style, with the fruits of many years' labour in Jamaica, in which the symptoms and treatment of the disease are unpretendingly laid down, and the text judiciously preserved from all extraneous matter. Limited as we are for space, we cannot go so deeply into the subject of the Doctor's work, as from its importance, and its highly interesting nature, we are desirous of doing; but we should be wanting in our duty to the service, did we not call the attention of military surgeons to the value and utility of the contents of this volume—among which, not the least interesting is the "Medical Topography of the Military Stations of Jamaica." Any further recommendation from us might possibly be cavilled at, and we consequently shelter ourselves under the opinion of a medical friend, who has also enjoyed extensive opportunities of practice in Jamaica, and who gives his unqualified approbation to the work; while, as corroborative evidence that his opinion has not been vaguely formed, we have only to add that Sir James McGregor, Bart., Director General of the Army Medical Department, has permitted the treatise to be inscribed to him. With these very cursory remarks, we take leave of the very best work we have ever read on bilious remittent fever, its symptoms, treatment, and prophylaxis."

What, I again ask, must the world think of the man who writes the above in the year 1840, and in 1844 sets me forth to the world as a fool and a plagiarist?

Could he suppose me to be the fool he now politely designates me, when he could coolly and dispassionately write the following?—

"New North Street, Red Lion Square.
August 17, 1840.

"My Dear Arnold,—I rejoice that a Jamaica physician has vindicated the character of her practitioners, affected to be despised by the gravi atque doctes of the Great Babylon. You have at least shown them that we are not all 'Plantation Doctors, whose means of cure are the cart whip and salt water,' see Captain Southey's West Indies. I quote from memory, and hope I do not do that magnificent liar an injustice."

"Now, as to the use I purpose putting you to, it is twofold. We want both your penny and your pen—a Literary Newspaper to be published weekly. I will stick exclusively to the editorial department, you for the scientific, including medical papers."

Comment from me is unnecessary—an im-

partial public "will render unto Caesar the things which are Caesar's." The whole head and front of my offending, and which has unquestionably provoked all the unmerited and impotent abuse of Dr. Binns, is the failure of the Newspaper alluded to, a speculation which I was rashly prevailed upon to join in. This circumstance is only mentioned to point out how little dependence is to be placed upon such a person's integrity of purpose, and how little value is to be set on the writings of this calumnious and voluminous scribbler. The pages of the *Lancet* will certainly acquire no lustre from such scurrility as distils from the pen of Edward Binns, of whom I now take leave for ever.

INCREASED MORTALITY.

AMONG

CHILDREN UNDER THE HANDS OF UNEDUCATED PRACTITIONERS.

To the Editor of the Medical Gazette.

SIR,

It is only within the last two days, that I have had the opportunity of reading, in the *MEDICAL GAZETTE*, the letter of Mr. Leigh on the increased mortality of children under the hands of uneducated practitioners. His statement is in perfect accordance with an opinion I have long entertained on the same subject, as pursued in the town and neighbourhood where I have my own residence, and which I had previously partially embodied in a letter addressed, last week, to the Editor of the *Lancet*.

My observations were elicited by the proposed Medical Reform Bill of Sir James Graham; wherein I confined myself especially to what I consider, at the present time, a most prevailing and increasing source of mischief to the profession, and danger to the public; namely, the *practising druggists*; for, as to quackery under the usual acceptance of the term, I look upon it as of minor importance. There have always been, and ever will be, quacks or boastful pretenders in every profession, art, and science, and vain would it be to attempt to put them down in medicine. Not so, I trust, with the druggist: he, it is true, proceeds on the same general principle as the quack, the *si vult populus*; and if it were only an innocent deception, it might be allowed to pass; but, when it comes to a matter of life and death, it assumes a more serious character. It would redound much more to the credit of the druggist if he were to act upon another maxim, "*ne vultor ultra crepidam*;" for when he does get beyond the last, he makes sad work of it; but then avarice prompts him; the pocket or till

wants replenishing! Has he, then, no conscience? Oh! yes, a little, a very little! For example, it hath, not unfrequently, happened to myself, as doubtless it hath to numberless others in the profession, that a patient has applied for gratuitous advice, especially a poor woman with a sick child. On the usual inquiry, if any advice hath been previously sought? Yes, sir, Mr. Such-a-one, a druggist, has seen it; but the child, instead of getting better, hath become so much worse, that Mr. — did not like to go on any longer, and so recommended me to come to you. Here, then, his conscience pricked him a little! and, if the child died, which was not very unlikely, he had the satisfaction to know that it fell to my lot to sign its passport, as it were, to another world. Then the druggist's conscience was quieted, and the poor mother in some measure satisfied: the disease was inevitably mortal; she had at last had the advice of a regular doctor, yet the child died!

I know not what the apothecaries were in the days of Pope, but the druggists of the present day remind me of the following lines:—

"So modern 'pothecaries taught the art,
By doctors' bills* to play the doctor's part;
Bold in the practice of mistaken rules,
Prescribe, apply, and call their masters fools."

Now, sir, these lines, *nomine mutato*, only substituting druggists for apothecaries, become perfectly applicable at the present time. The cap would indeed, I think, fit more closely; for we cannot but suppose that the latter had something of a regular medical education, whereas the generality of the former have had none but that of compounding behind the counter; and yet have they the assurance to prescribe for, and even to visit, patients; besides which, each has his own family pill,—antibilious forsooth,—bile being the present fashionable order of the day!

I am aware of the difficulty of legislating on this subject; yet, when the gratuitous services of the medical profession are, as they ought to be, taken into consideration, and that they form the only class of society who do any thing gratuitously, surely they must be entitled to every protection the law can give them. It would not be possible, nor right, to prevent the druggist from selling his pennyworths of salts, jalap, rhubarb, and so forth; nevertheless, there should be a penalty attached to his prescribing for, and particularly visiting, patients; and this penalty should be adjudged, and summarily inflicted by the magisterial bench; the complaining party should not be forced on the remedy of a tedious and expensive law-suit: this latter circumstance is, doubtless, the delinquent's safeguard.

We occasionally read of a regular prac-

titioner put on his trial for, and convicted of, malapraxis! Ought, then, the uneducated druggist to escape? He knows the several articles of the *materia medica*, indeed, their physical qualities, and perhaps their physiological effects, though this does not follow; but of their use in given circumstances, wherefore one should in any case be preferred to another, he is generally profoundly ignorant! Ought such a man, I say, to be allowed to escape with impunity for presumptuously meddling in matters of no less moment than those of life and death?

However the gross errors and fatal consequences of the uneducated may be legalized by enactment, or countenanced by non-enactment, they never can be the less morally criminal; nor indeed can the government be a good or a just government that does not essay at least to prevent them. I have now to apologize for thus intruding upon your, probably, more valuable time, and am, sir,

Your very obedient and humble servant,
MEDICUS PROVINCIALIS.

September 18th, 1844.

STHENIC AND ASTHENIC DISEASES.

To the Editor of the Medical Gazette.

SIR,

IN your GAZETTE of the 13th September is an article on "The Absurdity of Modern Doctrines in regard to Sthenic and Asthenic Diseases," wherein the writer forms a scale of degrees somewhat on the principle of a thermometer or other meter; taking for granted that it is essential, as in that instrument, that the middle degrees in the scale must be passed through to get from the top to the bottom. I think that his premises are quite incorrect, and that a scale of that kind can only be justly applied to the certain sciences, such as where the links in the chain are always persequent, and not as in pathology, or rather physiology, where the links or states between sthenic and asthenic diseases cannot be said even to be defined, and much less justly that health is *between* them; for I should say that a *disease*, whether sthenic or asthenic, existing in such a complicated machine as the human body, where one function hangs so much on another, cannot be said to be an exalted state of vital power, but a perversion of it; and it is well known that bleeding in some apparently asthenic states, as enteritis, will produce a sthenic state, but health does not *intervene* between these, but *follows* a happy termination of both. As I before said, Mr. Earle has made the mistake of applying the laws of a fixed science to an uncertain one.—I am, sir, yours, &c.

GUYENSIS.

Guy's Hospital, Sept, 21, 1844.

* Bills, Medical Recipes.

INCISION OF THE PERINEUM, PERFORMED FOR ABSCESS OF THE PROSTATE.

By M. LALLEMAND.

A MAN, 30 years of age, had been affected for a month with an enlargement of the prostate. Pus was observed on the instrument which had been used in sounding him; he was in a low and weak state, and had hectic fever, with turbid urine. On an examination by the rectum, no resisting swelling was felt in the situation of the prostate, but a cavity conveying the sensation as if it contained matter. M. Lallemand considered this to be a case of abscess of the prostate; he thought its contents could not be readily discharged, because the surrounding parts could not compress the abscess sufficiently to bring its fibrous walls into apposition, and the urine, by constantly penetrating into the abscess, would prove a never-failing cause of inflammation, or at any rate, an obstacle to its absorption. The indications of cure appeared to be to prevent the urine passing into the abscess, to change the chronic into acute inflammation, and then to bring the parietes into contact. An incision was made in the perineum along the raphé, and carried to the neck of the bladder; the prostate was then freely opened, which gave exit to some fetid pus. The pulse was accelerated on the night of the operation, but the next day the patient was free from fever. On the sixth day, nitrate of silver was applied to the wound, and repeated every two or three days. The urine gradually passed by the urethra, and the patient was soon cured.—*Gazette Médicale*, September 7.

In the following case a new operation was performed by M. Pétrequin, to prevent the occurrence of the serious evils which sometimes follow severe contusions of the perineum.

On the 3d of January, 1844, an adult fell on a narrow platform from a height of nine feet; all the shock came on the perineum, which immediately began to swell, and retention of urine followed. On the 5th, when he was taken to the Hôtel Dieu, M. Pétrequin observed a large sanguineous effusion extending from the rami of the pubes to near the coccyx, a contused wound at the upper part of the scrotum, the integuments of a reddish black colour, as in impending gangrene; anxiety, thirst, &c. Having reflected on the generally fatal termination of cases of this description, M. Pétrequin determined to prevent infiltration of the urine, and on the 6th he introduced a catheter into the bladder, but with so much difficulty that he was satisfied the urethra had been injured. An incision was then made on the median line, and carried down to the catheter. The knife reached the

catheter in the middle of the membranous portion, and the urethra was divided to allow the introduction of the *lithotome caché*. The catheter was then withdrawn, and M. Pétrequin opened the blade of the lithotome so as to divide only the point of the prostate, after which some urine passed; but it was necessary to throw into the bladder an injection of luke-warm water to remove the clots of blood which obstructed the wound, when the urine came away freely. A large gum-elastic sound was then introduced into the bladder through the wound, and allowed to remain. The next day the sanguineous effusion of the perineum and scrotum had decreased, the integuments were not so red, and the urine came through the wound. On the 12th of January, a few drops of urine came away by the natural passage, and the effusion had almost entirely disappeared. The catheter in the perineum was removed on the 15th, and replaced by one in the urethra, which was allowed to remain. On the 8th of February, the wound in the perineum was quite healed, and the patient restored to health.—*Gazette Médicale*, September 7th.

THE SPONTANEOUS CURE OF PHTHISIS.

By C. T. COLLINS, M.D.

[In the September Number of the New York Journal of Medicine, just received, there is a case headed as above, which is interesting taken in connection with the views of our ingenious friend, Mr. Robinson, which were published in last week's Gazette. It is possible that this case of Dr. Collins may have been one of empyema; yet the gurgling sounds are perfectly characteristic of a cavity in the substance of the lung, and the case may have been one of genuine tubercular phthisis affecting the right lung only.—Ed.]

"It is my belief that there are many more cases of phthisis pulmonalis cured by nature alone than medical men are generally aware of. I do not mean to say that we should always trust to nature alone, by any means, but that we should be very cautious lest we do too much. The case that I am about to relate came under my care the 29th day of March last. Sarah Hamor, æt. 55, born in England, had always been rather delicate. She was attacked last fall with erysipelas of the left hand and arm; and after recovering from that, she caught a severe cold, which was followed by a troublesome cough, and shooting pains through the chest, but more especially on the right side, from the right mamma to the shoulder-blade of the same side. She now began to lose flesh; and when I first saw her (which was as above stated) she was so much emaciated, to use a common phrase, that she was a mere skeleton. She was so weak, at that time, that she was

unable to help herself; she had profuse night sweats, severe cough, and expectorated about half a pint or more of light greyish yellow pus of a frothy nature (same as usually seen in the last stages of consumption) in the course of twenty-four hours. Her shoulders were raised and brought forward; the chest flat, and the clavicles very prominent, leaving a hollow. On auscultation there was that peculiar hollow gurgling sound, at times, heard over the right lung; and, at others, there was no sound to be heard of respiration at some points. The dyspnoea sometimes became so urgent that the friends several times thought her dying. Almost as soon as she fell asleep, she would break out in a profuse perspiration, and the little sleep she did get was not refreshing. There was an abscess on the right side of the spine, extending from about the second rib to the ninth or tenth, and about four inches wide, involving all the muscles of the back contained within that space. There was an opening about an inch and a half from the spine, over the region between the fifth and sixth ribs, which I enlarged by means of a bistoury, and kept open by the use of poultices. The abscess discharged constantly, and at one time nearly a pint of well-marked pus. When I was first called, I told the friends that I thought she could live but a very short time, which conclusion, I was informed, all parties concerned had come to before having had her brought into town.

She had been brought over the river from Wallabout, L. I., the same day that I first saw her—it being her desire to be at her friend's house, in this city, when her spirit should take its flight. My great object in her case was to palliate her sufferings, and merely make her as comfortable as possible during the time she might live. I told her friends to let her eat as much as she wanted, and anything in the way of ordinary food; also to let her have a small quantity of wine. Ordered the following mixture to be given at night, and at any time during the day when the cough was most troublesome: \mathfrak{R} Gum. Acaciæ, Ext. Glycyrrhis. \mathfrak{a} \mathfrak{a} \mathfrak{z} j., Syr. Altheæ, Tinct. Opii, \mathfrak{a} \mathfrak{a} \mathfrak{z} ss., Vin. Antimo. gtt. x., Aquæ puræ, \mathfrak{z} ij. Dose, cochleare l. magn. I visited my patient daily, expecting every visit to be the last, for about a fortnight, when I was convinced that she was no worse: her night sweats began to decrease, and she got more refreshing sleep; her appetite seemed very good, and in fact it was rather voracious, and her cough was easier. The discharge from her back began to diminish, and at the end of four weeks was quite healed up. Her cough had nearly left her at that time, and she began to gain flesh. In about four weeks from the time I first saw her, her cough had entirely left her, and she was gaining strength fast. The

only thing that she now complained of was pain about the right side, and a 'falling in,' as she said, of the right side of the chest, which she had observed during the whole course of treatment. The right side became much smaller than the left, owing to the chest's shaping itself to the new condition of the lung. In about six weeks from the time I first saw her she left town for Poughkeepsie, in better health, she said, than she had enjoyed for years. I gave her nothing of any importance besides cough mixtures, similar to the one first ordered.

There is certainly something very singular in this case, and some may be led to believe that there were no tubercles in the lungs, the affirmative of which I have every reason to believe, for I never saw a plainer-marked case. The left lung seemed, from the first, not to be diseased."—*New York Journal of Medicine.*

In answer to "An Enquirer," Clause the 28th of the Bill provides, "that any person legally practising as a physician, surgeon, or apothecary, at the time of the passing of this Act, shall be entitled to have his name registered as a physician, surgeon, or licentiate in medicine and surgery, on producing his diploma, license, or certificate."

MORTALITY OF THE METROPOLIS.

Deaths from all causes registered in the week ending Saturday, September 14.

Dropsy, Cancer, Diseases of Uncertain Seat	84
Diseases of the Brain, Nerves, and Senses	132
Diseases of Lungs and Organs of Respiration	197
Diseases of the Heart and Blood-vessels	21

WILSON & OGILBY, 57, Skinner Street, London

INDEX to VOL. XXXIV.

(VOL. II. FOR THE SESSION 1843-44.)

A.

- Abercrombie's, Dr. James, cases of hæmorrhage of the liver, 507, 792.
- Abortion, remarkable, related by Dr. Bæde, of Fredricksund, 271.
- Abscess, mammary, in the fifth month of pregnancy, Mr. B. Phillips on a case of, successfully treated, 317; of the septum narium, simulating polypus, recovered from, 318.
- Abscess of the tongue, Dr. Møller on a case of, 320.
- Abscess, scrofulous, of the neck, Dr. Hoffman's case of, with perforation of the jugular vein, 206.
- Absurdities of mesmerism, by "An Unbelieving Spirit," 704.
- Academy of Sciences, Paris, subject of the prizes of the, for 1845, 32.
- Acephalocysts, Mr. Rose on, 525.
- Adams, Mr. John, on fungus cerebri, 337.
- Address on commencing a new volume, 20.
- Address from the members of the Royal College of Surgeons of England to the Council of that College, 123.
- Addison, Mr. W. on the transformation of pus-cells into a mucous or fibrous tissue, 650, 691, 725.
- Age and mortality, constitution as to, of the Royal Academy of Medicine of Paris, and Council of the Royal College of Surgeons of England, 175.
- Albuminous urine, Dr. Heaton on some cases of, 27.
- Alison, Dr. on the causes of epidemic fever in Scotland, 449.
- Alcohol, Dr. Golding Bird on the presence of, in the urine, 690.
- Allnatt, Dr. on the nature of tic douloureux, 830.
- American Editor's travelling experience among his countrymen, 63.
- Anasarca, extensive, Mr. Fearnside's report of a case of, with albuminous impregnation of the urine, 545.
- Anatomy act, remarks on a recent attack on the, in the House of Commons, 381.
- Anatomical questions, are physicians competent authorities or not on? 87.
- Aneurism, Mr. Hey's case of, of the external iliac, in which a ligature was applied to the common iliac artery, 93.
- Aneurism, dissecting, of the aorta innominata, Dr. Todd's case of, 350.
- "Anglus," history by, of the true theory of menstruation, 109.
- Ankle, Mr. W. Lyon on disarticulation at the, 301.
- Anniversary meeting of the Provincial Medical and Surgical Association, held at Northampton, full report of the proceedings at the, 667.
- Apology and plea of the Company of Apothecaries, 200.
- Apothecaries' Hall, lists of gentlemen who have received certificates, 32, 96, 128, 176, 208, 272, 320, 352, 384, 416, 448, 480, 544, 576, 608, 672, 752, 784, 816, 848, 880.
- Apothecaries, the, of Bruges, 320.
- Apoplexy, Dr. Mayo on a case of, dependent upon disease in a remote organ, 15.
- Arm at the shoulder-joint torn off by machinery, case of recovery after, 59.
- Arnold's, Dr. reply to Dr. Binn's calumnies, 876.
- Arnott's, Dr. James, case of empyema, with observations on the operation of paracentesis thoracis, 596.

- Arsenic, Dr. Shearman on the tests and antidotes of, 187.
- Arteries, pulmonary, Mr. Paget on the obstructions of, 94.
- Artery, deep femoral, Dr. J. C. Hall's case of wound of the, 115.
- Astragalus, Mr. Hancock on dislocations of the, with the lower end of the tibia and fibula inwards, 24.
- Atlee's, Dr. case of successful peritoneal section for the removal of two diseased ovaria, complicated with ascites, 49.
- Aubinais, M. case of polypus of the uterus, adherent to the placenta, successfully removed, 848.
- Author, the modest, 381.
- B.
- Bachelor of medicine, gentlemen who have passed their first examination for the degree of, 672.
- Badeley's, Dr. case of paraplegia treated with strychnine, 496.
- Banat fever in Hungary, 511.
- Barlow, Dr. on adherent pericardium, 47.
- Barlow, Dr. on a case of tumor in the right hypochondrium, occurring after injury, from which a large quantity of fluid resembling bile was repeatedly withdrawn by the operation of tapping, 267.
- Barlow, Dr. of Bath, notice of the decease of, 64.
- Barker's, Mr. T. Herbert, case of inversion of the uterus, with remarks, 9, 43.
- Belany, remarks on the late trial of, for the murder of his wife, the value of the medical evidence given, with observations on the importance of educated medical men to the community, 745.
- Bell, the late Sir Charles, pension to the widow of, 637.
- Bernard, M. on the functions of the spinal nerve, 447.
- Bernard's, M. experiments upon section of the eighth pair, 512.
- Bernard, M. Claude, on the gastric juice, and its influence on nutrition, 126.
- Bennett, Dr. J. R. on the causes, nature, diagnosis, and treatment of acute hydrocephalus, 441.
- Bermann's, Dr. case of inflammation of the spinal marrow, 383.
- Bethlem Hospital, increase of the salaries of the physicians to the, 505.
- Bile, Professor Schwann's researches concerning the importance of, in the living animal organism, 692.
- Bill for the better regulation of medical practice throughout the United Kingdom, 661.
- Bird's, Dr. Golding, elements of natural philosophy, reviewed, 569.
- Bird's, Dr. Golding, remarks on Professor Liebig's views of the composition of the urine, 685.
- Bird's, Dr. Frederic, case of the successful removal of a diseased ovary of three years' duration, 655.
- Bissell's, Dr. Emery, cases of ovarian disease, 544.
- Blindness, counterfeit, Sir George Lefevre's account of a case of, involving a caution to spectators of mesmeric exhibitions, 599.
- Blister, M. Darcq's speedy way of raising, 672.
- Blood, circulation of the, Mr. Robinson on certain points in the mechanism and physiology of the, 426, 487, 519.
- Blood, Mr. Addison on coagulation of the, 726.
- Blood-letting, universality of the taste for, in Naples, 174.
- Boards of Guardians, the Horse-Guards, and the Admiralty, versus the Medical Profession, 502.
- Books, analyses and notices of:—
- Dumas and Boussingault on the chemical and physiological balance of organic nature, 19.
- Mr. Swan on the principal offices of the brain and other centres, 52.
- Mr. Shaw's account of Sir C. Bell's classification of the nervous system, 53.
- Dr. W. Tyler Smith on scrofula, 87.
- Mr. Hare's practical observations on the prevention, causes, and treatment of curvatures of the spine, 117.
- Guy's Hospital reports, 160, 269.
- Dr. Wood's homoeopathy unmasked, 197.
- Dr. Weiss's hand-book of hydropathy, 198.
- Dr. Wilson's practice of the water-cure, 200.
- Dr. Metcalf on caloric, its mechanical, chemical, and vital agencies in the phenomena of nature, 229, 303, 405.
- Dr. Rigby on dysmenorrhoea, and other uterine affections, 342.
- Dr. D. B. Reid's illustrations of the theory and practice of ventilation, 375.
- Wagner's elements of comparative anatomy, 409.
- Dr. J. R. Bennett on the causes, nature, diagnosis, and treatment of acute hydrocephalus, 441.
- Enchiridion medicum, or a manual of the practice of medicine, the result of fifty years' experience, 465.
- Mr. Turner's anatomico-surgical observations on dislocations of the astragalus, 500.
- Dr. J. R. Smyth's miscellaneous contributions to pathology and therapeutics, 534.
- Dr. Golding Bird's elements of natural philosophy, 569.

- Dr. Kemp's letter to Professor Liebig on some misrepresentations contained in the second edition of his work entitled *Animal Chemistry*, 590.
- Mr. Curling's practical treatise on the diseases of the testis, 629.
- Thomas Sydenham, M.D. opera omnia, edidit Guilielmus Alex. Greenhill, 660.
- Dr. Wagner's elements of physiology, edited by Dr. Willis, 707.
- Mr. Morton on calculous concretions on the horse, ox, sheep, and dog, 736.
- Dra. Marx and Willis on the decrease of disease effected by the progress of civilisation, 738.
- Mr. A. S. Taylor's manual of medical jurisprudence, 771.
- M. Louis' researches on phthisis, 808.
- Mr. Fownes' Actonian prize essay, 833.
- Dr. Bull's hints to mothers, 865.
- Bossey's, Mr. cases of poisoning by *anacardium*, 288.
- Boyd, Dr. on the necessity of effecting exchanges in the County Asylums of recent and curable cases of insanity for chronic and incurable cases, 842.
- Boyle's, Dr. remarks on the report laid before the government of New Brunswick on the leprosy prevailing in certain French settlements in that province, 609.
- Brain, Dr. Wallis on the long issue of the scalp in diseases of the, 271.
- Brain, Mr. Whitehead on diseases of the, terminating fatally, the result of coup de soleil, or insolation, 677.
- Bredow's, Dr. account of a case in which he divided the *portio dura*, 319.
- Breast, fibrous tumor of the, 63.
- Brodie, Sir Benjamin, elected corresponding member of the Royal Academy of Sciences, Paris, 32.
- Brown's, Mr. case of scirrhus of the thyroid gland, 349.
- Buchanan, Dr. A. on fibrine and its transformations, 529.
- Buchanan's, Dr. A. note on the formation of fibrine, 720.
- Buhring's, Dr. case of bicephalous monstrosity, in which one of the heads was removed by ligature, 29.
- Bull's, Dr. hints to mothers, 865.
- Bullock, Mr. Lloyd, on the preparations of iron, 63.
- Baude's, Dr. account of a remarkable abortion, 271.
- Bursæ, suppurating, in the sole of the foot, Mr. C. Hawkins on a case of, 278.
- Burnett, Sir William, letter from, on the claims of naval surgeons to be included among the Fellows of the College of Surgeons, 718.
- Burton, Dr. on a new method of making medicated tinctures, 734.
- Cæsurus and acephalocysts, Mr. Rose on, 525.
- Calculi in the bladder, Mr. Coulson on the causes of occasional failure in the detection of, 321.
- Cancer, fatality of, particularly of operations performed for its removal, 416.
- Cancer, and diseases resembling cancer, clinical lecture on, by Mr. C. Hawkins, 385.
- Cancer of the pylorus, Mr. Fearnside's case of, treated in University College Hospital, 476.
- Cannabis Indica, Mr. Ley on the effects of, 159.
- Carbon, Mr. Rigg on the formation or secretion of, by animals, 702.
- Carpenter, Dr. William, elected Fullerian professor of physiology to the Royal Institution of Great Britain, 544.
- Carriere, M. on blood-letting in Naples, 174.
- Carus, Dr. on the present state of cranioscopy, upon a scientific foundation, 625, 680, 723, 765.
- Catamenia, Dr. Greenhow on the effects of opium on the, 117.
- Charter of the Royal College of Surgeons, statement relating to the, 314.
- Chabrely's, M. remedy for incontinence of urine, 448.
- Chemistry, Professor Liebig on the importance of, 513.
- Chloride of magnesium recommended by Dr. Lebert as an aperient salt, 208.
- Cholera, Dr. Merriman's statistical records of the progress of, throughout the globe, 472.
- Cholera in India, Mr. Clark on the treatment of, 17.
- Civilisation, Dr. Marx on the decrease of disease effected by the progress of, 37, 101, 180, 296, 324.
- Clark, Mr. on the treatment of cholera in India, 17.
- Clark, Dr. on the origin and treatment of syphilis, 470.
- Cod's liver oil, substitute for, proposed by M. F. Dubois, 415.
- Collins, Dr. on the spontaneous cure of phthisis, 879.
- College of Surgeons, address from the members of the, to the council, 123.
- College of Surgeons, proceedings at the meeting of the Fellows for the election of new Councillors, 603.
- College of Surgeons, parliamentary papers relative to the, 718.
- College of Surgeons, lists of gentlemen admitted members, 32, 96, 128, 176, 208, 240, 272, 320, 384, 416, 448, 480, 512, 544, 576, 608, 672, 752, 784.
- College of Physicians, new Fellows of the, 512.

- Glanders, acute, M. Landouzy's case of, following the bite of a horse, 816.
- Goodfellow's, Dr. S. J. case of fever, in which animalcula were found in large numbers in the contents of the stomach, and in the blood, 724.
- Grades in professions, editorial article on, 23.
- Grantham, Mr. John, on the great inconvenience to medical men of long attendance at sessions and assizes, 267.
- Greenhow, Dr. on the effects of opium on the catamenia, 117.
- Green's, Dr. Hennis, cases of tubercle of the lungs in children, with some remarks on infantile consumption, 506.
- Greek leprosy in Sardinia, M. Trompeo on the, 608.
- Gregory's, Dr. George, notes of a case of vitiligo infantilis, 24.
- Grinding system, editorial observations on the, 89, 120.
- Griffiths', Dr. case of hydatids of the liver and abdomen, 585.
- Gruby, M. on the cryptogamic vegetable which constitutes the contagious disease described under the names *teigne tondante*, or *hermes tonsurans*, 171; on certain cryptogamic vegetables developed in great quantities in the stomach in a case of dysphagia and chronic vomiting, 171.
- Gulliver, Mr. on the use of the supra-renal glands, and on fatty matter, 411.
- Guthrie, Mr. and his colleagues in the Council of the Royal College of Surgeons of England, 572.
- Guy's Hospital reports, 2d series, No. 3, analysis of, 160, 259.
- H.
- Hall's, Dr. J. C. case of wound of the deep femoral artery, 115.
- Hall's, Dr. J. C. practical hints on the treatment of hare-lip, 830.
- Hæmorrhoids, report of the case of a patient afflicted with, treated in the Westminster Hospital, with remarks by Mr. B. Phillips, 173.
- Hæmorrhage from perforation of the arch of the aorta by false teeth impacted in the œsophagus, Dr. Duncan's case of, 351.
- Hæmorrhage from the liver, Dr. James Abercrombie's cases of, 507, 792.
- Hæmorrhoids and their treatment, M. Lisfranc on, 31.
- Hancock, Mr. on dislocations of the astragalus, with the lower end of the tibia and fibula inwards, 24.
- Hare-lip, Dr. J. C. Hall's practical hints on the treatment of, 830.
- Harveian oration, by Dr. Ogle, remarks on the, 466.
- Hare's, Mr. practical observations on the prevention, causes, and treatment of curvatures of the spine, 118.
- Hawkins's, Mr. Cassar, clinical lectures:—On injuries and diseases of the spine, 209. On a case of strangulated inguinal hernia, 241. On a case of ossific formation in muscles, 273. On contraction of the fingers of both hands, 277. On suppurating burrs in the sole of the foot, 278. Cancer, and diseases resembling cancer, 385. On hydrophobia, 417.
- Heaton, Dr. on different forms of granular disease of the kidney, 27.
- Heaton's, Dr. case of inflammation and gangrenous abscess of the lungs following a state of partial asphyxia produced by a poisonous dose of opium, 132.
- Heart, Mr. Fearnside's report of a case of hypertrophy and dilatation of the, 677.
- Health inspections, remarks on, by an army surgeon, 541.
- Hernia, strangulated inguinal, Mr. C. Hawkins's clinical lecture on a case of, 241.
- Hernia, or protrusion of the intervertebral substance, Mr. T. W. King on, as a cause of paraplegia, 337.
- Hewett's, Mr. Prescott, account of the cases of strangulated hernia treated in St. George's Hospital in 1842 and 1843, 269.
- Hewett's, Mr. Prescott, cases of spina-bifida, with remarks, 459.
- Hey's, Mr. Richard, case of aneurism of the external iliac, in which a ligature was applied to the common iliac artery, 93.
- Hoffmann's, Dr. midwifery case: twins—footling presentation, 205; case of paralysis of the organs of sense after scarlatina, 208; case of scrofulous inflammation of the neck, 201.
- Horse and Foot Guards, petition of the medical officers of the, to the House of Commons, for an alteration in the charter lately granted to the Royal College of Surgeons of England, 636.
- Hoskins, Dr. on the introduction of the solutions of lead into the bladder for the decomposition of phosphatic calculi, 413.
- Hôtel-Dieu, the, fifty years ago, 318.
- Hufeland's, C. W. *enchiridion medicum*, reviewed, 465.
- Hull, Dr. on the division of medical labour, 402.
- Humanity, indiscriminating, of medical men, 96.
- Humboldt, Baron, anecdote of, 96.
- Humoralism in fever, inflammation, and irritation, Mr. T. W. King on, 553.
- Hydrophobia, clinical lecture, by Mr. C. Hawkins, on a severe case of, treated in St. George's Hospital, 417.

Hydropathic and homœopathic institutions, Professor Liebig's opinion of, 480.
Hydatids of the liver and abdomen, Dr. Griffith on a case of, 585.
Hymen, imperforate, Dr. Shultice's case of, 62.

I.

Ileus, Dr. Mayo's report of cases of, 145.
Ileus, case of, from turning or twisting of the bowel on its axis, 61.
Imperforate hymen, Dr. Shultice's case of, 62.
Inflation of the lungs of an undelivered infant successfully performed, 671.
Inflammation, Mr. T. Wharton Jones's report on the present state of knowledge of the nature of, 80.
Inflammation, Mr. J. W. Earle on, 135, 604, 831.
Injection of the uterus as a means of expediting and facilitating delivery, 527.
Insanity, Dr. Mansfield on the statistics of, in the Duchy of Brunswick, 95.
Insanity, puerperal, Dr. Mayo on, 436.
Insanity, Dr. Boyd on the necessity of effecting exchanges in the county asylums of recent and curable cases of, for chronic and incurable cases, 842.
Intussusceptio, case of, 272.
Iodine, treatment of leucorrhœa by means of the tincture of, 544.
Iodide of potassium, Dr. Oke on the therapeutical powers of, 320.

J.

Jeaffreson, Dr. S. J. on the pathology and treatment of ovarian diseases, 586, 645, 696, 795, 858.
Jenner and Napoleon, anecdote of, 176.
Jones, Dr. H. Bence, on the oxalic acid diathesis, 92.
Jones's, Mr. T. Wharton, report on the present state of knowledge of the nature of inflammation, 80.
Jones's, Mr. T. Wharton, account of a microscopical examination of an early corpus luteum, 623.

K.

Kasloff, Dr. on contraction of the foramen lacrum posterius, in maniacs and suicides, 95.

Kemp, Dr. George, on the formation of fat, 696.
Kemp's, Dr. letter to Professor Liebig on some misrepresentations contained in the second edition of his work entitled "Animal Chemistry," reviewed, 490.
Kidney, Dr. Heaton on different forms of granular disease of the, 27.
King, Mr. T. W. on the progressive development of the osseous bodies of the vertebrae and sternum, 73.
King, Mr. T. W. on humoralism in fever, inflammation, and irritation, 553.
Kirk's, Mr. case of dislocation of the metatarsus, 440.
Koechny, M. on a case of ileus from a turning or twisting of the bowel on its axis, 61.

L.

Labour, editorial observations on the excessive division of, in the practice of medicine, 345.
Labour, medical, Dr. Hull on the division of, 402.
Lacroix, M. on the general laws regulating the displacement of fractures, 258.
Lactéal vessels, elective powers of the, 94.
Lafargue, M. on the inoculation of veratrine in neuralgia, 784.
Landouzy, M. on a case of acute glanders following the bite of a horse, 816.
Lane, Mr. present to, 575.
Larrey, Baron, anecdote of, 96.
Lebert, Dr. on chloride of magnesium as an aperient salt, 208.
Lebert's, Dr. microscopical and physiological researches into the nature of tubercle, 238.
Lee's, Mr. Henry, report of fatal diseases and morbid appearances observed in the post-mortem examinations made at St. George's Hospital during the year 1843, 154, 190.
Lefevre's, Sir George, case of obstruction in the intestinal canal, terminating favourably on the ninth day by spontaneous vomiting and evacuation of the contents of the intestine, 26.
Lefevre, Sir George, on the constitution of the medical profession at home and abroad, 497.
Lefevre's, Sir George, account of a case in which blindness was counterfeited, involving a caution to spectators of mesmerism exhibitions, 599.
Leg, lacerated wound of the, Mr. Phillips on a case of, in which erysipelatous inflammation and gangrene supervened, and proved fatal, 316.
Leprosy in Sardinia, M. Trompeo on the, 608; Dr. Boyle's report on the disease as prevailing in New Brunswick, 609.

- Leigh, Mr. John, on the increased mortality among children under the hands of uneducated practitioners, and from want of all medical attendance, 781.
- Leroy, M. on the utility of operations in the cancerous diathesis, 237.
- Lesaing's, M. account of a case in which the vagina and neck of the uterus were double, for which a section was made of the vaginal septum, and delivery accomplished by the forceps, 847.
- Leucorrhœa, treatment of, by means of tincture of iodine, 544.
- Lever, Dr. on the frequent association of puerperal convulsions with albuminous urine, 216.
- Ley, Mr. on *Cannabis Indica*, 159.
- Liebig, Professor, on the importance of chemistry, 512.
- Lisfranc, M. on hæmorrhoids and their treatment, 31.
- Lithectasy, Dr. J. G. Wright's case of, 77.
- Lithotomy, the operation of—a modern Cheselden! 558.
- Liver, Dr. James Abercrombie's cases of hæmorrhage from the, 507, 792.
- Liver, Professor Weber upon the minute structure of the, 670.
- Louis', Dr. P. C. A. researches on phthisis (*Sydenham Society's* edition), reviewed, 808.
- Lunatic Asylum at Hanwell, clinical instruction at, 638.
- Lungs, Dr. J. D. Heaton's case of inflammation and gangrenous ulcer of the, following a state of partial asphyxia produced by a poisonous dose of opium, 132.
- Lymphatic vessels, Dr. Willis on the function of the, 65.
- Lyon, Mr. William, of Glasgow, papers by:—
On disarticulation of the ankle, 301.
On fractures of the vertebræ, 337, 392.
On a case of encephalocèle, or hernia cerebri, 493.
Cases of fracture of the maxillæ, 550.
On fracture of the pelvis, 613.
- M.
- MacDonnell's, Dr. contributions to the diagnosis of empyema, 344.
- Mania, Dr. Sharkey on the employment of digitalis in, 337.
- Mansfield, Dr. on the statistics of insanity in the duchy of Brunswick, 95.
- Maniacs and suicides, Dr. Kasloff on contraction of the foramen lacerum posterius in, 96.
- Marx, Dr. on the decrease of disease through the progress of civilization, 37, 101, 180, 296, 324.
- Marx's, Dr. and Dr. Willis's essay on the decrease of disease effected by the progress of civilization, reviewed, 738.
- Marylebone and Paddington Hospital, 572.
- Mayo's, Dr. record of cases treated at the St. Marylebone Infirmary, with remarks:—case of apoplexy, dependent on disease in a remote organ, 15; case of gastrodynia, 70; ileus, 145; pseudo-rubeola, 226; phlegmasia dolens, 400; puerperal insanity, 436.
- Medical profession, editorial observations on the present state and future prospects of the, 234, 377, 409, 444, 468, 569, 634, 665, 710, 777, 809, 837, 867.
- Medical Bill, the new, "Scrutator's" observations on the, 715.
- Medical practice, bill for the better regulation of, throughout the United Kingdom, 660.
- Medical profession, Sir G. Lefevre on the constitution of the, at home and abroad, 497.
- Medical profession, numbers of the, in Great Britain, 784.
- Medical Protection Assembly, remarks on their address by "A Lover of Order," 237.
- Medical education, editorial observations on, 310.
- Menstruation, history of the discovery of the theory of, 109.
- Menstruation, Dr. Power on the theory of, 217.
- Menstruation, theory of, 271.
- Meningitis, Dr. Gillkrest's sketch of the, as it appeared at Gibraltar in the early part of 1844, 453.
- Merriman's, Dr. statistical records of the progress of cholera over the globe, 472.
- Mesmeric exhibition, notes of a, 529, 564.
- Mesmerism, exposure of, 574.
- Mesmerism, editorial observations on the recent exhibitions of M. Marcillet and Alexis, 535, 600.
- Mesmerism, on the absurdities of, by "An Unbelieving Spirit," 704.
- Mesmeric skill in escaping from difficulties, 640.
- Metatarsus, Mr. Kirk's case of dislocation of the, 440.
- Metcalfe's, Dr. work on caloric, its mechanical, chemical, and vital agencies in the phenomena of nature, reviewed, 229, 303, 405.
- Metempsychosis, the modern, 415.
- Mialbe, M. on the proximate cause of diabetes, 174.
- Microscopical Society, abstract of a paper read at the, by Mr. John Quekett, on some phenomena connected with the movement of the cilia in the common mussel, 170.
- Midwifery reports, by Dr. F. H. Rambotham, 142, 196, 225, 251, 279, 287, 368, 398, 438, 463, 483, 517, 619.

- Midwifery, statistics of: cases occurring in the private practice of Mr. Waddington, 144.
- Military hygiene, Mr. Roberts on, and particularly on the clothing of soldiers, 513, 641.
- Military statistical reports, 607.
- Modes of getting on and off in America, 32.
- Mollities ossium, Mr. Solly's cases of, 472.
- Moir, Dr. Andrew, notice of the decease of, 64.
- Monstrosity, bicephalous, Dr. Buhning's account of a case of, in which one of the heads was removed by ligature, 29.
- Monstrosity, Dr. Francis' account of an unusual form of, 580.
- Monneret, Dr. E. on the treatment of articular rheumatism by tincture of colchicum, nitre, and blood-letting, 206.
- Morbus Brightii, Dr. G. Owen Rees on the, and various forms of anæmia, 652.
- Morel-Lavallée, M. on the production of false membranes from the mucous surface of the bladder, under the influence of cantharides applied to the skin, 783.
- Mortality in the metropolis, tables shewing the, 32, 64, 96, 128, 176, 208, 240, 272, 320, 352, 384, 416, 448, 480, 512, 544, 576, 608, 640, 672, 720, 752, 784, 816, 848, 880.
- Mortality, quarterly table of, 640.
- Mortality among children, Mr. Leigh on the increase of, under the hands of uneducated practitioners, and from want of all medical attendance, 781.
- Mortality, influence of wealth and property on, 672.
- Morton's, Mr. J. T. treatise on calculous concretions in the horse, ox, sheep, and dog, reviewed, 736.
- Movement in the profession respecting Sir James Graham's bill: resolutions passed at a meeting in the Borough of St. Mary-lebone, 744; copy of a petition from the physicians, surgeons, and apothecaries of Leamington, in Warwick, 745; meeting at Queen's College, Birmingham, 815; at Bedford, 815; at Bath, 839; at Leeds, 841; at Hereford, 841; at Kidderminster, 870; at Hastings and St. Leonard's, 870; at Chelsea, 870; at Norwich, 871; at Epsom, 871; Birmingham Medical and Surgical Association, 871.
- Mulder, Professor, on the physiological chemistry of proteine, and its compounds, 823, 852.
- Necessity of highly educated men as practitioners of medicine, 264.
- Nerves of the gravid uterus, not examined by Dr. W. Hunter, 55.
- Nerves of the uterus, letters on the subject of the, 575.
- Neuralgia, M. Lafargue on the inoculation of veratrine in, 784.
- Notes of a mesmeric exhibition, 529, 564.

O.

- Obituary: Dr. Andrew Moir, of Aberdeen, 64; Dr. Barlow, of Bath, ib.; Dr. Elliot, of Carlisle, 544.
- Edema glottidis, case of, treated in the Westminster Hospital, for which tracheotomy was performed, but which proved fatal, with remarks by Mr. B. Phillips, 173.
- Oenanthe crocata, Mr. Bossey's cases of poisoning by, 288.
- Oke, Dr. on the therapeutical powers of iodide of potassium, 320.
- Oleaginous urine, Dr. T. O. Ward's case of, 125.
- Omentum, case of fatal injury of the, 128.
- Operations, M. Leroy on the utility of, in the cancerous diathesis, 237.
- Operations on the root of the tongue, new mode of procedure in, 30.
- Opium, Mr. C. Taylor on the effects of, on infants, 19.
- Opium, Dr. Greenhow on the effects of, on the catamenia, 117.
- Ossific formations in muscles, Mr. C. Hawkins's clinical remarks on, 273.
- Ovary, the human, Dr. C. Ritchie's contributions to the physiology of the, 7, 137, 253, 281, 370.
- Ovary, diseased, Dr. F. Bird's case of the successful removal of a, of three years' duration, 655.
- Ovarian diseases, Dr. S. J. Jeaffreson on the pathology and treatment of, 586, 645, 696, 795, 858.
- Ovarian disease, Dr. Bissell's cases of, 544.
- Ovarian cysts, Mr. B. Phillips's observations on the recorded cases of operations for the extraction of, 473.
- Ovaria, diseased, Dr. Atlee's case of successful peritoneal section for the removal of, complicated with ascites, 49.

N.

- Neapolitan medical practitioner, the, and Neapolitan medicine, 239.
- Necrosis of the lower jaw, Mr. Sharp's case of, recovered from without deformity, 350.

P.

- Paget, Mr. on obstructions of the pulmonary arteries, 93.
- Paget's, Mr. account of the dissection of a cyst containing seminal fluid, 470.

- Paget's, Mr. translation of Prof. Mulder's account of the physiological chemistry of proteins and its compounds, 823, 852.
- Paracentesis thoracis, Dr. Hamilton Roe on, as a curative measure in empyema and inflammatory hydro-thorax, 166.
- Paraplegia, Dr. Badeley's case of, treated with strychnine, 498.
- Paterson, Mr. on a case of puerperal convulsions in a twin case, in which artificial delivery was successfully performed, 331.
- Paterson's, Mr. case of accidental uterine hemorrhage in which the membranes were ruptured, and large doses of ergot of rye administered, 833.
- Pathological specimens, preservation of, 61.
- Pelvis, Mr. Lyon's observations on fracture of the, with a case, 613.
- Pension to the widow of Sir C. Bell, 637.
- Percy's, Dr. John, cases of diabetes mellitus, with precise observations concerning the influence of animal diet upon the urine, 147, 322.
- Pereira, Dr. note from, disclaiming any connexion with "The Medical Mutual Life Assurance Society," 384.
- Perspiration, Professor Valentin on the amount of, from the human body, 544.
- Pericardium, adherent, Dr. Barlow on, 47.
- Phillips's, Mr. Benjamin, observations on the recorded cases of operations for the extirpation of ovarian cysts, 473.
- Phthisis, M. Louis' researches on, reviewed, 808.
- Phthisis pulmonalis, Mr. George Robinson on the surgical treatment of, 828.
- Physicians practising generally, 383.
- Pigne, M. on the preservation of pathological specimens, 61.
- Poisoning by ananthe crocata, Mr. Bossey's cases of, 238.
- Poisoning by digitalis, Mr. George Wilson's case of, 659.
- Polypus of the larynx, M. Ehrmann on a case of, for which laryngotomy was successfully performed, 205.
- Portio dura, Dr. Bredow's case of division of the, 319.
- Porter, Mr. on the treatment of medical men by Boards of Guardians, 203.
- Posthumous fame of medical men, 83.
- Power, Dr. on the theory of menstruation, 217.
- Preparations of iron, Mr. Bullock on the, 63.
- Prescott, Mr. on the origin of syphilis, 175.
- Pring's, Mr. F. B. case of disease of the colon, 857.
- Profession, on the state of the, in the provinces, by a Provincial Surgeon, 270.
- Proteine and its compounds, Prof. Mulder on the physiological chemistry of, and its compounds, 823, 852.
- Pseudo-rubeola*, Dr. Mayo's report of a case of, 226.
- Puerperal convulsions, Dr. Lever on the frequent association of, with albuminous urine, 216.
- Puerperal convulsions in a twin case, for which artificial delivery was successfully performed, 331.
- Puerperal insanity, Dr. Mayo on, 436.
- Pus-cells, Mr. W. Addison on the transformation of, into a mucous or fibrous tissue, 650, 691, 725.

Q.

- Quarantine, M. Aubert Roche on, 59.
- Quekett, Mr. John, on some phenomena connected with the movement of the cilia in the common mussel, 170.

R.

- Ramsbotham's, Dr. F. H. reports on the Royal Maternity Charity:—for the year 1832, 142; for 1833, 196; for 1834, 225; for 1835, 251; for 1836, 279; for 1837, 327; for 1838, 368; for 1839, 398; for 1840, 438; for 1841, 463; for 1842, 485; for 1843, 517; tabular view of the cases admitted from Jan. 1, 1831, to Dec. 31, 1843, 619.
- Ramsbotham's, Dr. F. H. reply to Mr. Waddington's inquiry as to the correctness of the return of the number of forceps cases occurring in the Eastern district of the Royal Maternity Charity, 758.
- Rectum Infirmary, and its founders, again, 445.
- Rees, Dr. G. Owen, on the pathology and treatment of the *Morbus Brightii*, and various forms of *emania*, 652.
- Reflecting prism, Dr. Warden on a new application of the, 257.
- Regulation of the Medical Profession Bill—the anatomy act, 380.
- Reid's, Dr. D. B. illustrations of the theory and practice of ventilation, reviewed, 375.
- Reid, Dr. on two cases of tubercular expectoration from the bronchi in the adult, 411.
- Respiration, M. Guy-Lussac on the chemical phenomena of, 177.
- Rethinitis, acute, Mr. W. White Cooper's cases of, caused by the use of the microscope, 469.
- Retroversion of the uterus, Mr. James Whitehead on a case of, in its unimpregnated state, with paralysis of the bladder, 803.
- Reward of scientific men in this country, 347.

- Rheumatism, articular, Dr. E. Monneret on the treatment of, by tincture of colchicum, nitre, and blood-letting, 206.
- Rheumatism, acute articular, Mr. Fearnside's report of a case of, treated in University College Hospital, 548; another case of, complicated with endocarditis, 580.
- Rigby, Dr. on dysmenorrhœa, and other affections, reviewed, 342.
- Rigg, Mr. on the formation or secretion of carbon by animals, 702.
- Ritchie's, Dr. Charles, contributions to the physiology of the human ovary, 7, 137, 253, 281, 370.
- Roberts, Mr. on military hygiene, and particularly upon the clothing of soldiers, 513, 641.
- Robinson, Mr. George, on certain points in the mechanism and physiology of the circulation of the blood, 426, 487, 519.
- Robinson, Mr. George, on the surgical treatment of phthisis pulmonalis, 838.
- Roche, M. Aubert, on quarantines, 59.
- Roe, Dr. Hamilton, on paracentesis thoracis as a curative measure in empyema and inflammatory hydro-thorax, 166.
- Rose, Mr. on œnurus and acephalocysts, 525.
- Royal Medical and Chirurgical Society, papers read at the:—
- Dr. George Gregory's notes of a case of vitiligo infantilis, 24.
- Mr. Henry Hancock on dislocations of the astragalus, with the lower end of the tibia and fibula inwards, 24.
- Sir G. Lefevre's case of obstruction in the intestinal canal, terminating favourably on the ninth day by spontaneous vomiting and evacuation of the contents of the intestine, 26.
- Dr. Pence Jones on the oxalic acid diathesis, 92.
- Mr. Hey's case of aneurism of the external iliac, in which a ligature was applied to the common iliac artery, 93.
- Mr. Paget on obstructions of the pulmonary arteries, 94.
- Dr. Hamilton Roe on paracentesis thoracis as a curative measure in empyema and inflammatory hydro-thorax, 166.
- Dr. Theophilus Thompson's account of a case of empyema which recovered after repeated punctures of the pleural sac, 167.
- Mr. Barlow on a case of tumor in the right hypochondrium, occurring after injury, from which a large quantity of fluid resembling bile was repeatedly withdrawn by the operation of tapping, 267.
- Mr. Prescott Hewett's table of the cases of strangulated hernia occurring in St. George's Hospital in 1842 and 1843, 269.
- Dr. Todd's case of dissecting aneurism of the aorta, innominata, and right carotid arteries, causing suppression of urine, and white softening of the right hemisphere of the brain, 348.
- Mr. Brown's case of scirrhus of the thyroid gland, 349.
- Mr. Sharp's case of necrosis of the lower jaw recovered from without deformity, 350.
- Dr. Reid's two cases of tubercular expectoration from the bronchi in the adult, 411.
- Dr. Hoskins on the introduction of the solutions of lead into the bladder for the decomposition of phosphatic calculi, 413.
- Mr. W. White Cooper's case of acute retinitis, caused by the use of the microscope, 469.
- Dr. Clark on the origin and treatment of syphilis, 470.
- Mr. Paget's account of the dissection of a cyst containing seminal fluid, 470.
- Mr. Smith's proposals for the improvement of diagnosis in the investigation of the diseases of the uterus, 471.
- Mr. Worthington's case of fistulous communication between the intestinum ileum and urinary bladder, simulating stone in the urethra, 471.
- Mr. Solly's cases of mollities ossium, 472.
- Dr. Merriman's statistical records of the progress of cholera over the globe, 472.
- Mr. B. Phillips's observations on the recorded cases of operations for the extraction of ovarian cysts, 473.
- Dr. Hennis Green on cases of tubercle of the lungs in children, with some remarks on infantile consumption, 506.
- Dr. Warren on a peculiar case of gelatiniform cancer, in which all the organs in the body contained colloid tumors, 507.
- Dr. Abercrombie on a case of hæmorrhage of the liver, 507.
- Royal Academy of Sciences, Paris, prizes awarded by the, to M. Stromeyer and M. Dieffenbach, 60.
- Royal College of Surgeons, election to the Fellowship of the, 236.
- Royal College of Surgeons, statement relating to their new charter, 314.
- Royal College of Surgeons of Ireland, their licentiates, and the medical profession generally, settled in Ireland, 163.

S.

St. George's Hospital, Mr. Henry Lee's report of fatal diseases and morbid appearances observed in the post-mortem examinations made at, during 1843, 154, 190.

- St. George's Hospital report:—two cases of fracture of the skull, with observations, 605.
- St. George's Hospital, distribution of prizes, 125.
- St. Marylebone vestry, the, and their gratuitous medical officers, 380.
- St. Marylebone Infirmary, and its medical officers, 505.
